The second species is a spreading tree, with the branches and twigs irregular and twisting, more horizontal than in the first: the leaves ovate, serrate, the younger ones pubescent underneath: the stipules linear: the flowers in terminating, sessile, villose umbels, white, finely tinged with red on the outside: the fruit roundish, umbilicate at the base, and acid. It is a native of Europe.

In its wild state it is called the Crab or Wilding, and is armed with thorns, as well as the Wild Pear. Miller mentions two varieties in

the fruit of the Crab, one white, the other purple towards the sun; but it is commonly yellowish green with a tinge of red. And also a variety with variegated leaves.

There are a great many varieties of the Apple, but the following are given by Mr. Forsyth as the most deserving of attention:

The Acklam's Russet, which is a small Yorkshire apple, of a russet colour toward the sun, and yellow on the other side; it becomes ripe in January, and keeps till March.

The Aromatic Pippin, which is a very good apple, of a bright russet next the sun; and the flesh has a fine aromatic flavour. It ripens in October.

The Baxter's Pearmain, which is a real Norfolk apple, of a handsome size, and pale-green colour, full of small dark spots. It is a fine kitchen fruit, and will keep till April. It is also a good eating apple.

The Beauty of Kent, which is a fine large apple, resembling a Codlin. It is streaked with a fine red towards the sun, and of a beautiful yellow, with some streaks of red on the other side. It is a very good apple, coming into eating in September, and keeping till the latter end of April.

The Belle Grisdeline, which is a new seedling raised at Norwich, of much beauty, and never failing to afford crops. It was first propagated by Mr. Lindley, about seven years ago, who gave it this name. It is a handsome apple, resembling the Bursdoff, of a yellow colour, with red toward the sun, and an excellent table apple, keeping till March.

The Bell's Pearmain, which is a real Norfolk apple, large and handsome; red toward the sun, and yellow on the other side. It is a fine kitchen fruit, and pretty good to eat raw, keeping till June.

The Best Pool, which is a middle-sized apple, of a pale-green colour, streaked with red towards the sun. It is a good apple, in eating from January to April.

The Black Apple, which is a middle-sized fruit, of a dark mahogany colour next the sun, but fainter on the other side. It is of a pleasant sweet taste, keeping till the middle of April.

The Bland's Summer Pippin, which is a handsome apple, of a gold colour, and an agreeable flavour. It is a great bearer, ripe in September, and keeps till Christmas.

The Blatche's fine small Table-Apple, which is about the size of a small Golden Pippin; red toward the sun, and green on the other side. It has a sugary taste, and comes into eating in January.

The Boomrey, which is a pretty large handsome

apple, of a flat shape, and deep-red colour; and the flesh is streaked with red. It is not fit to eat raw, but will do well for cider, or for the kitchen. It keeps till April.

The Bovey Redstreak, which is a handsome apple, of a flattish shape, beautifully streaked with a bright red next the eye, which is small, and of a yellow colour about the footstalk. It keeps till the latter end of October.

The Broad-eyed Pippin, which is a fine large flat apple, with a very large eye; the colour is a greenish-yellow, with a little red toward the sun. It is a good apple, and keeps till May.

The Brandy Apple, which is about the size of a Golden Pippin, flat-shaped, and of a yellowish russet colour. It is of a pleasant flavour; comes into eating in January, and keeps till March.

The Bursdoff, or Queen's Apple, which is a beautiful fruit, red next the sun, and of a fine yellow on the other side. It is a very fine apple; in Mr. Forsyth's opinion, next in perfection to the Golden Pippin, and about the same size. It is in eating from November to the end of March.

The Cadbury Pound, which is a middle-sized apple, of a light-green colour. It is of a good flavour; ripening in January, and keeping till March.

The Carnation Apple, which is a beautiful middle-sized fruit, finely striped with red. It is ripe in January, and keeps till May.

The Carbury Pippin, which in size and shape resembles the French Crab, and is of a deep green colour. It is a good baking apple, keeping till March.

The Caraway Russet, which is a handsome russet-coloured apple, about the size of a Nonpareil.

The Calville, Red and White, which are good apples, and of a vinous taste. Some have a red and some a white pulp, the white being reckoned of a most delicious taste. They are in eating in September and the following month.

The Cat's Head, which is a large oblong apple, of a greenish-yellow colour, with a little brownish red next the sun; sometimes the colour inclines to a russet. It is a good baking apple, and is in eating from October to December.

The Cockagee, which is a conical-shaped middle-sized apple, red on that side next the sun, and of a fine yellow colour on the other. If properly managed, the fruit keeps till February. It is a famous cider apple, and also bakes well.

The Codlin, which is generally the first apple that is brought to market. Its fruit is so well known that it needs no description. It is

in eating from July to December; and is good either for baking or boiling.

The Cornish Nonpareil, which is rather under the middle size, is a little flattened, and of a russet colour. It is a very good apple, and keeps till the middle of March.

The Cornish Pearmain, which is of a middling size, and long shape; of a dull green colour on one side, and russet on the other. It is a very good apple, and keeps till the latter end of April.

The Court-of-Wick Pippin, which is described by Mr. Billingsly, in his "Survey of Somersetshire," as "the favourite apple, both as a table- and cider-fruit, taking its name from the spot where it was first produced. It originated from the pip or seed of the Golden Pippin, and may be considered as a beautiful variety of that fruit. In shape, colour, and flavour, it has not its superior: the tree is large, handsome, and spreading, and a very luxuriant bearer. On the whole, it cannot be too strongly recommended." It is larger than the Golden Pippin, of a yellowish-green colour, and a little tinged with red next the sun. It comes into eating in January.

The Cockles Pippin, which is a handsome oval-shaped apple, below the middle size, of a russet colour, mixed with yellow and red. It keeps till April.

The Corpendu, or Hanging Body, which is a very large apple, and has a red cast on the side towards the sun; but is pale on the other side. It takes its name from always hanging downwards; and comes into eating in September.

The Dalmahoy Pippin, which is about the size of a Golden Pippin, of a green colour, and a little streaked with red towards the sun. It has a tolerably good flavour, rather sharp; and is in eating from September to February.

The Dimock's Red, which is under the middle size, of a fine red colour, intermixed with a little yellow on the side from the sun. It is ripe in January, and keeps till March.

The Dredge's Seedling, which is a fine large apple, striped with red next the sun, and of a yellowish-green on the other side. This is an excellent kitchen apple, of a pleasant taste, and keeps till the latter end of January.

The Dredge's Beauty of Wilts, which is a beautiful apple, of a good size, and one of the finest yet known in point of general utility. It is of a fine bright yellow colour, spotted with red towards the sun; and has an excellent vinous flavour. It is good either for the table or baking, and keeps till March.

The Dredge's Russet, which is a small apple,

of a greenish-russet colour, and of a pleasant flavour. It is ripe in November, and keeps till Midsummer.

The Dredge's White Lily, which is a fine apple, of an exceeding high flavour, and keeps till March.

The Dredge's Fair Maid of Wishford, which is a fine middle-sized apple, of a yellowish-green colour, with some russet next the sun, and of an excellent flavour. It is a great bearer, and is in eating from Christmas to Easter, being an excellent dessert apple.

The Dredge's Queen Charlotte, which is a beautiful middle-sized apple, of a gold colour, with red towards the sun. It is of an exquisite flavour, comes into eating about Christmas, and keeps till February.

The Dredge's Fame, which is a good-sized apple, red towards the sun, and streaked like the Ribston Pippin on the other side. It is a most excellent apple, being in eating from Easter to Midsummer.

The Dumpling Apple, which is a handsome apple, and rather above the middle size, flat-shaped, and of a greenish-yellow colour, with some faint streaks of red. It keeps till March.

The Dutch Queening, which is a large apple, somewhat resembling the Cat's Head in shape. The colour is red next the sun, and green on the other side, with sometimes a little red. The fruit is fit only for the kitchen, and for making cider. It is ripe in January, keeping till the end of March.

The Elton's Yellow Kernel, which is a handsome middle-sized apple, of a yellow colour. It is a good table apple, being in eating from January to March.

The English Rennet, which is a handsome apple, beautifully streaked with red, but darkest towards the sun; of a tolerable flavour, but apt to grow mealy when kept too long. It keeps till the middle of May.

The Embroidered Apple, which is pretty large, and the stripes of red very broad, from which circumstance it takes its name. It is commonly used as a kitchen apple, becoming ripe in October.

The Everlasting Striped Apple, which is below the middle size, of a conical shape. The colour is a striped green towards the footstalk, and red towards the eye.

The Fameuse, which is a pretty large apple, of a beautiful dark red, with a little yellow on the side from the sun. Its flesh is very white, and full of a rich sugary juice; coming into eating about the latter end of October. It was introduced from Canada by Mr. Barclay of Brompton.

The Fenouillet, ou Pomme d'Anis, the Fennel or Anise Apple, which is a middlesized fruit, of a gray colour; the pulp is tender, and has a spicy taste, like aniseed. It becomes ripe in September and October.

The Flower of Kent, which is a large handsome apple, of a yellow colour, and pretty good flavour. It keeps till the middle of April.

The Fox-whelp, which is a small apple, streaked with red. It is ripe in January. It is a cider apple.

The Franklin's Golden Pippin, which is a handsome middle-sized apple, of a conical shape and gold colour, beautifully marked with dark spots. The fruit has a fine aromatic flavour, and deserves the first place at the table; but it is a shy bearer. It comes into eating about the middle of November.

The French Crab, which is a large handsome apple, of a deep green colour, with a little red next the sun. It will keep all the year; is a good baking apple, and, if the summer be warm, pretty good for eating, and is a great bearer.

The French Codlin, which is a pretty large apple, of a conical shape, and green colour, with red towards the sun, coming into eating in January.

The Fearn's Pippin, which is of the shape and size of a Nonpareil. It is of a beautiful scarlet next the sun, and of a golden yellow on the other side. It makes a fine show at table, and keeps till the latter end of February.

The French Spaniard, which is a large apple, in form of a hexagonal prism with the angles a little rounded, and of a yellowish-green colour: is pretty good, and keeps till the latter end of April.

The French or White Rennet, which is a large fruit, of a yellowish-green colour, with some gray spots. It has a sugary juice, and is good either for eating or baking.

The Gargey Pippin, which is a handsome conical-shaped apple, under the middle size, of a greenish yellow colour, with a little red towards the sun. This is a pretty good apple, and keeps till May.

The Gilliflower, which is a fine handsome apple, red towards the sun, and of a yellowish-green on the other side, having a fine flavour, and keeping till the latter end of March.

The Golden Rennet, which is a beautiful apple, a little flattened; of a fine red colour towards the sun, and yellow on the other side. It is a good eating apple, and keeps till February.

The Golden Russet, which is a fine middle-sized apple, of a golden-russet colour, from which it takes its name. It is a good apple, and keeps long.

The Golden Pearmain, which is a fine apple, above the middle size, of a fine deep red towards the sun, with a little yellow on the other side: when much exposed to the sun it is sometimes red all over.

The Golden Mundi, which is a fine handsome apple, beautifully streaked with red; of a good flavour, excellent for baking, and will keep till January. It is a good sauce apple.

The Golden Gloucester, which is a handsome middle-sized apple, of a flat shape, and gold colour, with red toward the sun. It is a good apple, and keeps till March.

The Golden Knob is a handsome though rather small apple, of a fine gold colour, sometimes inclining to a russet. It has a pleasant flavour.

The Golden Pippin is well known; and the French own it to be of English origin. It is almost peculiar to this country; for there are few countries abroad where it succeeds well. It is yellow as gold; the juice is very sweet; the skin (especially where exposed to the sun) is often freckled with dark yellow spots. It is certainly the most antient as well as the most excellent apple that we have. It ripens in October, and keeps through the winter. It has several sub-varieties.

The Godolphin Apple, which is a very handsome large fine fruit, streaked with red on the side next the sun, and of a yellowish colour on the other side. It is in eating from the latter end of September to December.

The Green Dragon, which is a fine large apple, of an excellent flavour, and pale-green colour. It is rather too large for the table, and is therefore mostly used as a kitchen apple. It keeps till March.

The Great or Large Russet, which is a middle-sized fruit, of a russet-colour, with a little dark-red toward the sun. A pretty good apple, and keeps till April.

The Griddleton Pippin, which is a large angular-shaped apple, of a green colour, with a little blush toward the sun. It is a baking apple, and keeps till March.

The Grumas's Pippin, which is about the size and shape of a Golden Pippin; of a dingy-green colour next the sun, and of a dull yellow on the other side. It is ripe in January, and keeps till April.

The Hagloe Crab, which is a yellow-coloured conical-shaped apple, below the middle size. It is ripe in January; but is only fit for making cider, or for baking.

The Hall Door, which is a fine large apple, of a flat shape, beautifully streaked with red toward the sun, and of a greenish-yellow on the

VOL. II.

other side. It is of a fine flavour, and is in eating from January till March.

The Hallingbury, which is a large flat-shaped apple, with large ridges from the base to the crown. It is of a beautiful red toward the sun, and of a yellowish colour on the other side and towards the eye.

The Hampshire Nonsuch, which is a pretty large well-shaped apple, of a greenish-yellow colour, streaked with red. It keeps till the latter end of November.

The Harvey's Russet, which is so called in Cornwall, is a large russet-coloured apple, with a little red toward the sun. It is a famous kitchen fruit, and tolerably good raw, with a musky flavour.

The Holland Pippin, which is a middle-sized apple of a flattish shape. Its colour is yellow, in some places inclining to green, with, sometimes, a little red toward the sun. It is a pretty good apple, keeping till the middle of April.

The Hollow-eyed Pippin, which is a middle-sized apple, of a yellow colour, beautifully spotted with red toward the sun; and the eye is pretty deep. It is a good sharp-flavoured apple, keeping till the middle of May.

The Hollow-eyed Rennet of Cornwall, which is a handsome flat-shaped apple, under the middle size, of a greenish-yellow colour, sometimes intermixed with russet. It is of an excellent flavour, and keeps till April.

The Hedge Apple, which is a new fruit, of middle size and handsome conical shape, red toward the sun, and of a straw-colour on the other side. It is of a tolerably good flavour, and keeps till the latter end of April.

The Hogshead Apple, which is a small red fruit; the flesh is red, and the taste austere. It is a cider apple, becomes ripe in January, and keeps till March.

The Hubbard's, or the Russet Pearmain, which is a real Norfolk apple; and, though not handsome, is one of the best table apples. It is of a dark russet colour, becomes ripe in January, and keeps till April.

The John Apple, which is a middle-sized handsome fruit, of a green colour, with a little red toward the sun; the foot-stalk being very small. It is an excellent cider and baking apple, from Devonshire; is of an excellent flavour, and keeps till March.

The Isle-of-Wight Pippin, which is a handsome middle-sized apple, of a greenish-yellow colour.

The Juneting, or Jenning, which is a small yellowish apple, red on the side next the sun. It is a pretty fruit for early variety, and ripens

2 R

about the latter end of June or beginning of the following month.

The Kernel Redstreak, which is of a greenish-yellow, with broad streaks of a dark-red all over it, and a yellow ground finely speckled with red next the sun.

The Kernel Pearmain, which is a small handsome apple, red toward the sun, and of a yellowish-green mixed with red on the other side. It is of a good flavour, keeping till the middle of May.

The Kentish Pippin, which is a good-sized apple, finely streaked with red. It is of a fine flavour, comes into eating about Christmas, and keeps till February.

The Kentish Nonpareil, which is a handsome flat-shaped apple, of a light-russet colour, inclining to red toward the sun. It is of a good flavour; and keeps till May.

The King of the Pippins, which is a middle-sized apple, of a fine gold colour, a little streaked with red towards the sun. It is ripe in January, and keeps till the latter end of March, when it becomes mealy.

The King Apple, which is a middle-sized apple, of a conical shape; and its colour is that of a beautiful red intermixed with a little yellow on one side. This apple is of a pleasant sugary taste, and keeps till the latter end of April.

The Kirke's Seedling, which is a large beautiful apple of a fine red colour towards the base, and yellow toward the eye. The footstalk is slender, and the eye large.

The Kirke's Scarlet Pearmain, which is a handsome middle-sized apple, of a beautiful red toward the sun, and a little yellow on the other side; becoming ripe in January.

The Kirke's Scarlet Admirable, which is a good apple for baking, and of a beautiful scarlet colour, is in eating about the month of January.

The Kentish Fill-Basket, which is a species of Codlin, of a large size, and generally used for baking. It is in eating from August to October.

The Kirton or Crack'd Pippin, which is a middle-sized apple, of a greenish-yellow colour, with little dark spots. The coat is generally rough toward the footstalk. It is a good apple for the table, coming into eating in September.

The Lady's Finger, which is an excellent table apple, of a conical shape; red next the sun, and of a yellowish cast on the other side, having a sweet pleasant flavour, and keeping till May.

The Large Styre, which is a handsome cider

apple, of a yellow colour, with a little red next the sun. It becomes ripe in November.

The Lisbon Pippin, which is a handsome middle-sized apple, of a flat shape, a fine red toward the sun, and of a reddish-yellow on the other side. The flesh is firm, and has a sharp pleasant taste. It comes into eating in November.

The Loan's Pearmain, which is a large oval-shaped apple, of a dull green colour intermixed with a brownish red, deepest next the sun. It is a pretty good table apple, of a sharp taste, ripening in September and keeping till May, but is apt to grow mealy.

The London Pippin, or Five-crowned Pippin, which is a fine large apple, of a green colour, streaked with red toward the sun. It resembles the Ribston Pippin, but is larger. It has a pretty agreeable taste; and will come into eating about the latter end of November. It is good for the kitchen and table; and a most abundant bearer. It keeps till the middle of April.

The Le Calville d' Automne, the Autumn Calville, which is a large fruit, of an oblong figure, and of a fine red colour toward the sun, having a vinous juice, and is much esteemed by the French.

The Long Laster, which is a middle-sized apple, of an angular shape, and fine yellow colour, with a beautiful red next the sun. It is of a tolerable flavour, and keeps till the middle of May, but is apt to become mealy.

The Lemon Pippin, which is a handsome oval-shaped apple, of a gold colour. It is of a fine flavour, and will keep till the beginning of March.

The Long Seam, which is a large angular-shaped baking apple, of a pretty good flavour, with light green colour. It keeps till the latter end of January.

The Lord Cheney's Green, which is a middle-sized Yorkshire apple, resembling the Yorkshire Greening. It is of a dark green colour, with a little of a chocolate colour next the sun. It is a baking apple, and keeps till the middle of May.

The Lord Arundel's Apple, which is large, of an angular shape; the colour is green, with a little dingey red toward the sun. It is from France, and good for sauce, keeping well.

The Lord Camden's Rennet, which is a good-sized seedling, of a yellow colour, with a little brownish red next the sun. It is a good-flavoured apple, and keeps till March.

The Lucas's Pippin, which is a handsome middle-sized, cylindrical-shaped apple, of a beautiful orange colour. It is a pretty good fruit, and keeps till the latter end of April.

The Maiden's Blush, which is a small apple, of a dark mahogany colour next the sun, but paler on the other side, and sometimes of a greenish cast. The taste is austere, and of course this fruit is not fit for the table; but does very well for baking, or for cider. It keeps till the beginning of March.

The Mansfield Tart, which is a large Nottingham apple, but most known in Yorkshire. It is handsome, of a green colour, having a little cast of a brownish red, with dark spots next the sun, being a baking apple, and keeping till February.

The May Gemmet, which is rather under the middle size, of a greenish-yellow colour, slightly streaked with red next the sun. It keeps till April.

The Major Hemmings's Apple, which is a handsome middle-sized fruit, of a light-green colour, with a little brownish-red towards the sun. It is an excellent apple.

The Margil, which is an excellent apple, about the size of a Nonpareil. It is of a red colour with some yellow on one side; continues in use from November to the latter end of March; and is often sold in the London markets for a Nonpareil.

The Margaret Apple, which is a fine and beautiful fruit, yellow striped with red, of a delicate taste, sweet scent, and generally eaten off the tree. It is ripe in August.

The Minchall Crab, which is a handsome middle-sized Lancashire apple, of a yellow colour, with some brown spots. It is common in the Manchester market, and keeps till April.

The Monstrous Rennet, which is a very large apple, turning red towards the sun, and of a dark-green on the other side. It is generally preserved on account of its magnitude, as the flesh is apt to be mealy. It becomes ripe in October.

The Mother Rennet, which is rather under the middle size, of a greenish colour, with a little blush towards the sun. The eye is large and deep, and the footstalk small.

The New-England Pippin, which is a large angular-shaped apple, of a green colour, with a little brownish-red towards the sun. It has a pretty good flavour, and keeps till March.

The Newtown Pippin, which according to Mr. Forsyth is an American Apple, but said to be originally from Devonshire. It is a fine large apple, of a greenish-yellow colour, and red, with dark spots next the sun. When much exposed, it is of a beautiful red towards the sun, and of a gold colour on the other side. It has a fine flavour when not kept till it is too ripe, as then it becomes mealy. It is in eating from November to January.

The New Red Must, which is a fine large apple, of a pale red towards the footstalk, and of a greenish colour towards the eye. It is a cider apple, and for baking.

The New Red Pippin, which is a beautiful middle-sized apple of a dark-red colour, with a mixture of yellow on the side from the sun. It keeps till March.

The Nonsuch, which is a good bearer, and very fit either for the table or kitchen; the cooks, however, complain that it makes but a very small proportion of sauce. It is ripe in September and October.

The Nine Square, which, according to Forsyth, is a Gloucestershire apple. It is a large angular-shaped fruit, of a fine red towards the sun, and yellow on the other side, with a small mixture of red, keeping till April.

The Norfolk Colman, which is a middle-sized apple, of a mahogany colour towards the sun, and a dark green on the other side. It keeps till August.

The Norfolk Beefin, which is a good-sized apple, rather flatted, of a deep red colour towards the eye, but paler towards the footstalk.

The Norfolk Paradise, which is a large apple, of a dark red colour towards the sun, and green on the other side. It is a nice baking apple, and of a tolerable flavour for eating. It keeps till the middle of May.

The Norfolk Storing, which is a pretty large apple, of a dark red colour towards the footstalk, and green towards the eye. It is of a pleasant sharp flavour, being in eating from the latter end of January to the latter end of April.

The Northern Greening, which is a fine oblong apple, full at the footstalk, of a pale-green colour, with a little red towards the sun. It is nearly of an equal size from the base to the crown, and has a fine flavour, being ripe in January.

The Nonpareil, which is a fruit deservedly valued for the briskness of its taste. It is seldom ripe before Christmas, and, if well preserved, will keep till May. It is justly esteemed one of the best apples that have been yet known.

The Oak Peg, or Oaken Pin, which is an oval-shaped middle-sized fruit, of a green colour striped with white. It is very full towards the footstalk, which is small, keeping till June.

The Old English Pearmain, which is an oval-shaped apple, of a middle size, and fine red colour, with a little yellow towards the eye. It is of a pleasant sweet flavour; and is in eating from January to March.

The Old Red Must, which is a fine large apple, somewhat resembling the New Red Must

both in shape and colour, with the addition of dark red spots toward the footstalk.

The Old Red Pippin, which is a middle-sized apple, red towards the sun, and of a greenish colour on the other side. It is a good apple, and keeps till March.

The Orange Pippin, which is about the size of a large Golden Pippin; of a beautiful gold colour, with a little pale-red towards the sun. It is a handsome apple, of a good flavour, and makes a fine appearance at table, being in eating in October, and keeps till March, but gets flat in the taste when too long kept.

The Orleans Pippin, which is a small flat-shaped apple, of a dark red colour; resembling the Orleans Plum.

The Paradise Pippin, which is a handsome middle-sized apple, of a reddish cast. It comes into eating in October, but will not keep. It grows mealy when too ripe.

The Pauson, which is below the middle size, of a conical shape, and of a greenish yellow or light green colour. It is ripe in January.

The Pile's Russet, which is a middle-sized longish-shaped apple, russet about the footstalk, yellow towards the middle, and of a brownish red about the eye. It is a very firm fruit, of a sharp acid flavour, being much esteemed for baking. It ripens in October, and will keep till April.

The Pigeonette, which is rather below the middle size, of a conical shape. It is of a pink colour, pretty dark towards the sun.

The Pearson's Pippin, which is a nice apple, about the size of a large Golden Pippin, of a yellowish colour, and the form a little flat. In Devonshire, according to Mr. Forsyth, they put these Pippins into the oven just after the bread is drawn, laying a weight over them to flatten them, in the same manner as they do the Beef in Norfolk, and bring them to table as a sweetmeat. It is a very good dessert apple, and keeps till March.

The Pomme Grise, which is a fine apple, from Canada, of a flattish form, and russet colour, streaked beautifully with red. It ripens late, and keeps till March. It is an excellent eating apple.

The Pomme d'Api, which is much valued for its colour, being of a bright red. The tree is a good bearer, and the fruit is not subject to be shaken with high winds. The fruit should be suffered to hang on the tree till October or November, if the frost do not set in. It comes into eating in February and March, and keeps long; but is more admired for its beauty than its flavour or fineness of taste.

The Pomme Violette, the Violet Apple, which

is a pretty large fruit, of a pale-green, striped with red towards the sun. It has a sugary juice, and a flavour of violets, from which it takes its name. It ripens in October, and continues in eating till February or later.

The Pomroy, or King's Apple, which ripens nearly as soon as the Juneting; and, though not so beautifully covered, is larger and much better tasted. It has a sub-variety, which is a winter apple.

The Pound Pippin, which is a large handsome apple of a greenish colour; and is good for baking. It becomes ripe in January.

The Poor Man's Profit, which is a dingey-coloured oval-shaped apple, below the middle size. It is raised freely from cuttings; and keeps till January.

The Queening, which is from Gloucestershire, is a large apple of an irregular shape, having large ridges from the base to the crown. It is of a dark red, but deepest towards the sun. It is a good cider apple, and bakes well, keeping till the latter end of November.

The Queening Kernel, which is a fine apple, above the middle size, of a deep red colour, covered very thick with small whitish specks. It is a tolerably good apple, and keeps till the latter end of April.

The Queen's Pippin, which is a small handsome apple, of a yellowish-green colour, sometimes inclining to red on the side next the sun. It is a fine flavoured apple, very fit for the table, coming into eating in January, and keeping till May; but is apt to grow mealy when kept too long. Mr. Forsyth says, "the tree never grows to the height of other apple-trees."

The Quince Apple, which is a middle-sized fruit, of a yellow colour, with a little red towards the eye. It is of a pleasant sharp flavour; ripe in January, and keeps till April.

The Ramborn, which is a large fruit, of a fine red next the sun, and striped with a yellowish green. It ripens about the middle of September.

The Red Pearmain, which is smaller than the Pearmain in general. It is of a deep red, with a little yellow on one side. A pleasant sweet apple; and keeps till the middle of April.

The Red Streak, which is a handsome middle-sized apple, beautifully streaked with red. It is a good cider apple, becoming ripe in January.

The Red Streak Seedling, from Longleat, which is from the Dorsetshire Red Streak, is a beautiful apple, of a yellow colour streaked with red, particularly next the sun. Forsyth says, it is sold in the Bath and Bristol markets in the latter end of September and begin-

ning of October. It is a pretty good apple, but does not keep long.

The Red Bag, which is a beautiful large Herefordshire apple, of a longish shape, streaked all over with a dark red; and is in eating about the middle of October.

The Red Must, which resembles the Old Red Must in shape; but is of a dark red colour towards the sun, and yellow on the other side. It is ripe about the middle of November.

The Requette Grise, which is a middle-sized fruit, of a gray colour next the sun; it is a very good juicy apple, of a quick flavour, and ripens about the latter end of October.

The Red Sweet, which is a small round apple, red towards the sun, and of a greenish-yellow on the other side. It is a good bearer, according to Forsyth, "and much esteemed among the country people of Cornwall for making a kind of tart or pie, one of their dainties at Christmas." It is a pretty good table apple, and keeps till March.

The Ribston Pippin, which is a fine apple, from Ribston Hall, near Knaresborough, in Yorkshire. It is a little streaked with red towards the sun, and yellow on the other side, being one of the best apples for eating and baking, and continues in use from the end of October till April. It bears very well as a dwarf, and no garden should be without it.

The Robinson's Pippin, which is about the size of a Golden Pippin, of a green colour, and partakes of the flavour both of a Golden Pippin and a Nonpareil. It keeps till May.

The Royal George, which is a fine large apple, of a beautiful yellow on one side and green on the other. It is a good apple, and keeps till June, but then grows mealy.

The Royal Nonpareil, which is a handsome apple, of a flatish shape, with a small footstalk and fine eye. It is about the size of a common Nonpareil, of a green colour, with red towards the sun. It is ripe in January, and keeps till the latter end of March.

The Royal Pearmain, which is a fine large apple, beautifully streaked with red. It is ripe in January and keeps till March, being a pretty good apple.

The Royal Russet, or Leather-coat Russet, which is a large fruit, and one of the best kitchen apples that we have. It is also a pleasant eating apple, and a great bearer, being in use from October to April.

The Russet Pippin, which is of a rough russet colour towards the sun, and of a green colour, sometimes inclining to yellow, on the other side. It is a good keeping apple, and fit either for baking or eating raw. It is ripe about

the beginning of February, and keeps till March.

The Red and White Calville, which are good apples, of a vinous taste; some have a red, and some a white pulp; and the white is reckoned of a most delicious flavour. They are in eating in September and October.

The Summer Pearmain, which is striped with red next the sun; the flesh is soft, but soon turns mealy; so that it is not much esteemed. It is in eating in August and September.

The Silver Pippin, which is a handsome middle-sized conical-shaped apple, of a fine yellow colour, with a faint blush towards the sun. The flesh is firm and very white, and of an excellent flavour. It keeps till the middle of May, or later.

The Seek no Farther, which is a handsome apple, rather above the middle size, of a pale-green colour, a little streaked with red. It is of a pleasant though not very high flavour; and is in eating from January to May; but is apt to be mealy when kept longer than the beginning of April.

The Sykehouse, which is a handsome middle-sized apple, from Sykehouse in Yorkshire, of an orange colour towards the sun, sometimes inclining to red, and yellow on the other side. This is a fine eating apple; ripe in January, and keeps till April.

The Stone Pippin, which is of a green colour streaked with red towards the sun. It is of a sharp taste, and is in eating from January till the middle of May.

The Stoup Codlin, which is a large handsome apple, of a pale-green colour, with a little red towards the sun. It is a baking apple, of a pleasant taste. It keeps till May.

The Striped Nonpareil Russet, which is a handsome apple, of a greenish-russet colour, with a little brownish-red towards the sun. It is about the size of a large Nonpareil, is ripe in January, and keeps till March.

The Spice Apple, which is a handsome middle-sized angular-shaped apple, of a yellow colour, and a pleasant flavour. It is ripe in January, and keeps till March.

The Skerm's Kernel, which is a conical-shaped middle-sized apple, beautifully streaked with red, deepest towards the eye, and having a good deal of yellow towards the footstalk. It is ripe in January, and keeps till March.

The Spice Rennet, which is a handsome apple, below the middle size, red towards the sun, and yellow on the other side.

The Spanish Pearmain, which is a middle-sized oblong apple, of a carnation colour, and dark-red towards the sun. It is a pretty good apple, and keeps till the beginning of May.

The Spanish Onion, which is a handsome round apple of a russet colour, with a dull red towards the sun. This apple, which is rather below the middle size, is very good for the dessert, keeping till March.

The Sharp's Russet, which is below the middle size, of a brownish-red colour towards the sun, and a pale green on the other side. It is shaped like the frustum of a cone; is of a pretty good flavour, and keeps till May.

The Spencer's Pippin, which is a middle-sized apple, of a yellowish colour, with many dark spots, being a baking apple, and keeping till the middle of May.

The Tankerton, which is a conical-shaped yellow apple, with sometimes a little blush towards the sun. It is an excellent sauce apple, and bakes well, being of an agreeable taste, but too large for the table. It will keep till February.

The Transparent Apple, which was introduced from St. Petersburg; but is more curious than useful: a tree or two, therefore, will be sufficient for a garden. It ripens in September and October.

The Treroider Renet, which is a small handsome russet-coloured apple, of an excellent flavour, and will keep till May.

The White Corpendu, which is a middle-sized long-shaped apple, of a yellowish colour. It is a good eating apple, and ripens in January.

The Ward Apple, which is a beautiful flat-shaped apple, rather below the middle size, of a fine red towards the eye, and of a yellowish-green towards the footstalk. It is a sharp-flavoured fruit, and keeps till June.

The Wheeler's Russet, which is of middling size, the flesh firm, and of a quick acid flavour; it is an excellent kitchen fruit, and keeps long. It ripens in October.

The Wine Russet, which is a middle-sized conical-shaped apple, of a dark russet colour, and sharp flavour. It keeps till the latter end of April.

The Wheeler's Extreme, which resembles the Pomme Grise, and is about the size of a Nonpareil. It is a flat-shaped apple, beautifully clouded with red on a yellowish-russet ground; is of an excellent flavour, and keeps till April.

The White Must, which is a middle-sized handsome apple, of a greenish-yellow colour, with a little red towards the sun; the flavour is rather tart, but agreeable. It is ripe in January.

The Whitmore Pippin, which is a good-sized handsome apple, streaked with red towards the sun, and of a pale yellow on the other side. It has firm flesh, of a tolerably good flavour, and is in eating from November to the latter end of April, or later.

The Wiltshire Cat's-head, which is a large handsome apple, red towards the sun, and green on the other side. It is a very fine baking apple, and of a good flavour, being ripe in January.

The Winter Pearmain, or Herefordshire Pearmain, which is of a fine red next the sun, and striped with red on the other side; the flesh is juicy, and stews well. It is fit for use in November, and if properly managed will keep till the latter end of March.

The Winter Pomroy, which is a pretty large conical-shaped apple, of a dark-green colour, a little streaked with red towards the sun. The coat is rather tough. It is a good baking apple, keeping till January.

The Winter Box Apple, which is a middle-sized fruit, of a light-green colour, and keeps till February.

The Woodcock, which is a good-sized apple, of a dark-red next the sun, and paler, with a little mixture of yellow, on the other side. It is ripe in January, and keeps till March, being a good cider apple.

The Wright's Nonpareil, which is a Salopian apple, being a great bearer, of a good size, and a little flattened. It is a good kitchen apple, and keeps till June. The tree is smaller in size than most other apple-trees.

The Yorkshire Greening, which is a good-sized flattened apple, of a dull-red colour, with a little green towards the eye. It keeps till August, or often later.

To these the following list has been subjoined, of useful Apples, for different purposes:

The Aged Pippin; the Aromatic Brooding, which is sometimes known by the title of the Summer Brooding; the Autumn Pearmain; the Barcelona Pearmain, the Beaufin, which are good for baking, and sometimes known by the names of the Lincolnshire Beaufin, the Yorkshire Beaufin, and the Norfolk Beaufin; the Black Moor, which is good for cider; the Bontradue, the Cawood Timely, which is good for eating; the Chardin's Sans-pareil, which is good for eating; the Chester Pearmain; the Costard, which is proper for cider; the Cotton Pippin, the Covadies, the Darling Pippin, the Derbyshire Crab, the Devonshire Buckland, the Double-blossom Scarlet Crab, the Dowsen's, the Dutch Paradise; the Early Nonpareil, also good for eating; the Everlasting Hanger, which is good for cider; the Eyer's Greening, also good for baking; the Frank Rambour, the Frazer's, the French Pippin, the French Paradise; the Gennet Moyle, good for cider; the Golden Doucet, the Golden Noble, the Golden Lustre, the Gray Noble, the Gray's Pippin; the Green

Blundrel, which is good for cider; the Green Pearmain, which is also proper for that liquor; the Havers's Monster, the Hay's fine large baking Apple; the Hertfordshire Under-leaf, which is fine for cider; the Hughes's New Golden Pippin, the June Keeping, the Kipling's Pippin, the Kirke's Incomparable; the Kitchen Rennet, good for baking; the Lancashire Housewife, useful in the same way; the Large Yellow Pippin, the Large Golden Pippin, good for eating, sometimes known by the name of *Baker's Golden Pippin*; the Large Apple Williamson, the Lawman's; the Lincolnshire Rennet, proper for baking; Lord Islay's Pippin, the Neal's Summer Kentish; the New England, good for baking; the New York Pippin, the Nutmeg, the Orgeline, or Orjeline; the Oxhead Pearmain, esteemed for eating, also known by the name of *Earl of Yarmouth's Pearmain*; the Pie Pie, the Pine-Apple Russet, the Pipy Russet, the Pomphilia, esteemed for eating; the Queen's Pearmain, the Red-fleshed Beaufin, the Red Vacan, the Ronald's Queen Charlotte; the Robine, good for baking; the Royal Wilding, proper for cider; the Scarlet Pearmain, the Sheppard's Russet, the Siberian Crab, the Sir Charles Wager's, the Spit, the Stout Buckland; the Striped Beaufin, which is good for baking; the Stubbard; the Styre, proper for cider; the Summer Redstreak, which is also used in the same way; the Summer Pippin, the Summer Russet; the Summer Colman, which is good for baking; the Summer Majetin, the Ten Shillings, the Tom Two Years Old; the Transparent Codlin, esteemed for baking; the Virgin; the White Pippin, good for eating; the White Sour, the Welch Lemon Pippin, the Whykins's Pippin, the Wine Sop; the Winter Redstreak, esteemed for cider; the Winter Colman, good for baking; the Winter Brooding, also proper for baking; the Winter Majetin, and the Yellow Buckland.

The sorts of apples advised for a small garden are the following: The Juneting, the Golden Pippins, the Nonsuch, the Ribston Pippin, the Nonpareils, the Queen's Apple, the Sykehouse, the Golden Rennet, the Aromatic Pippin, the Gray Leadington, the Scarlet Pearmain, the Lemon Pippin, the Pomme Grise, the French Crab, and different sorts of Russetins and Codlins, for baking.

There are other varieties and sub-varieties that may be equally valuable with many of the above.

The third is a tree which, when it blossoms in perfection, is highly ornamental. It blossoms about the end of April or beginning of May. The flowers are large, of a pale red when open,

and semi-double; the buds are of a much deeper hue. The fruit is sparingly produced, and of little value. It is probably a native of China.

The fourth species has a strong woody stem, sending out many side-branches, and covered with a smooth brown bark. The leaves are shaped like those of the cherry-tree; are of a deep green on their upper side, but paler on their under, slightly serrate, and on long foot-stalks. The flowers come out in bunches from the side of the branches on long slender peduncles; the petals are white, and shaped like those of the first sort, appearing in April; and are succeeded by roundish fruit, about the size of large Duke cherries, changing to a yellowish colour variegated with red, of a very austere taste, decaying like the fruit of the Medlar, and then more palatable. It is supposed to be a native of Siberia. There are varieties in the size of the fruit.

The fifth has the umbel on smooth peduncles. The calyxes are smooth on the outside; tomentose within: the leaves like those of the Apple, but more smooth, and more finely serrate, longer and narrower, and cut into acute angles on their sides. The flowers have a fragrant odour. It is a native of America, where the inhabitants plant them for stocks to graft apples upon. It flowers here in May.

The sixth species is a low crooked and distorted tree, covered with a brown bark, and much branched. The leaves are roundish or ovate, entire, above dusky green, underneath whitish, on short petioles. The flowers large. Corolla pale red or white. The calyx spreading, serrate, the length of the corolla. The fruit a pome, varying in shape in the different varieties—globular, oblong or pear-shaped. It is supposed a native of Austria &c.; flowering in May and June.

There are the following varieties:—The Pear Quince, with oblong-ovate leaves, and an oblong fruit lengthened at the base; the Apple Quince, with ovate leaves and a rounder fruit; the Portugal Quince, with obovate leaves, and an oblong fruit which is more juicy and less harsh than the others, and therefore the most valuable.

The Quince is a very beautiful tree when in flower, as well as when the fruit is ripe in the autumn, and was cultivated in this country at a very early period. According to Mr. Forsyth, "the best sort for planting in the fruit-garden is the Portugal, being the fittest for baking or stewing. It is of a fine purple colour when dressed, and is much better for marmalade than any of the other sorts. The oblong kind, and the Apple Quince, are also planted," he says

"in these situations, and other sorts are employed in the shrubberies for producing variety."

The above sort is likewise valuable for mixing with apples in making pies, puddings, &c. as they add a quickness to the flavour when flat.

Culture in the Pear kind.—These trees are raised by grafting and budding upon any kinds of pear-stocks; occasionally upon quince-stocks, and sometimes upon white-thorn stocks; but the first sort are preferable for general use to have large trees, and the second for moderate growers.

The numerous varieties of these trees having been first accidentally obtained from seed, and as these seedlings rarely produce the same sorts again, the approved kinds are continued and increased only by grafting or budding upon stocks raised from the kernels of the kinds just mentioned. In order to restrain the growth of these trees white-thorn stocks have also been used; but these are not so generally successful, and are almost in total disuse in the nurseries: of course pear-stocks are proper for general use, for principal large trees, both for walls, espaliers, and standards; and quince-stocks for smaller growths. For raising the stocks, the seeds or kernels of the different sorts should be sown in the latter end of autumn, as October, November, or December, or early in the spring, in beds of light earth, covering them near an inch deep; they come up in the spring: and in autumn, winter, or spring following, the strongest should be planted out in nursery-rows to remain for grafting and budding, for which, after having from one to two or three years' growth, they will be of proper size.

The operations of grafting and budding should be performed in the usual method; the former in the spring, and the latter in summer. See **GRAFTING** and **BUDDING**. For this purpose the grafts and buds should be procured from such trees as produce the finest fruit of the respective sorts; those designed as dwarfs for walls, espaliers, or standard-dwarfs, being grafted or budded near the bottom; and in those for half and full standards, the stocks may either be previously trained up from three or four to seven or eight feet high to form a stem, then grafted near the top, or be grafted low in the stock, like the dwarfs, and the first main shoot trained for a stem the above height: the grafted trees, both dwarfs and standards, shoot the same year, but the budded ones not till the spring after; and when their heads are two years old from the grafting and budding, they may, if thought proper, be planted out for good, or remain longer in the nursery, as may be found convenient.

The dwarfs for walls, espaliers, &c. whether they remain longer in the nursery, or be transplanted at a year old into the garden, should have the first shoots from the graft or bud, when a year old, headed down in March to five or six eyes, to force out a proper supply of four, six, or more lateral branches near the ground, to furnish the wall or espalier with bearers quite from the bottom, these readily producing others to cover the upper part.

Standards, supposing them to be grafted on high stocks, may either be headed near the top of the stock, or permitted to run up, as the case may require, so that if shortened it will force out laterals near the head of the stem, and form a more spreading full head; and if suffered to run up with the first shoots entire, they form higher and generally more upright heads in the end. Such standards, however, as are grafted or budded as low in the stock as for dwarfs, must have the first shoot trained upright at full length, six or seven feet high for a stem; if for full standards, they may either be topped at six feet height, to force out laterals near that part to form a spreading head, or suffered to run and branch in its own way to form a more erect and higher head.

The headed trees, both dwarfs and standards, on being cut down in the spring, soon branch out from all the eyes immediately below; when care should be taken during the summer to trim off all shoots from the stem, suffering all the top shoots to remain entire; when they will form handsome beginning young heads by the end of summer, and in autumn, winter, or spring following, may be finally planted out into the garden, &c.

When from necessity they are retained longer in the nursery, the whole should have proper pruning to reform irregular growths, and the different trees be trained accordingly, suffering the whole to branch away at full length, not shortening any after the above general heading down, when a year old, except it should seem occasionally necessary, either to reduce any casual irregularity, or to procure a more full supply of lower branches; after which no further general shortening should be practised to these sort of trees; for, after having obtained a proper set of regular branches near the head of the stem, they readily furnish more in their turn to increase the head on the upper part.

In regard to planting out the trees, they are mostly of proper growth for this purpose when from one or two to four or five years old, from the graft or bud; but if larger trees are required, those of six or eight years old may be safely

transplanted; younger trees, however, always succeed well, even when only two or three years old.

In selecting pear-trees for planting, Mr. Forsyth advises the choosing of the oldest trees that can be found instead of the young ones, and such as have strong stems; to have them carefully taken up, with as much of the roots as possible, and carefully planted, after cutting in the roots a little, spreading them as horizontally as can be done. Then to fill up all round the roots with light dry mould; forcing it in, about those which lie hollow, with a sharp-pointed stick; filling the whole up to the top without treading the mould, till the hole be first filled with as much water as it will contain, leaving it a day or two until the ground has absorbed the water; then to throw on some fresh dry mould and tread it as hard as possible, filling the hole up again with mould to within an inch of the top, and giving it a second watering, leaving the mould about three inches higher than the border, to settle of itself, and to receive the rain that falls, for at least a month. When the mould has become quite dry, it may be trodden a second time; then make a large bason all round the tree, and giving it another watering, mulching the top over with some rotten leaves or dung, continuing to water the trees once a week in dry weather, and sprinkling the tops frequently with a pot, or hand engine, to keep the wood from shrivelling till they have taken fresh root:—and where the trees are planted against a wall, the stems should stand sloping towards it; the lower parts of them being six inches from the bottom of the wall, to give them room to grow, as when planted close to the wall at bottom, the stems, in growing, will, he says, be confined on the back, grow flat, and be very unsightly. If any roots are in the way, to hinder it from being planted near enough to the wall, they must be cut off; at the same time taking care that the tree does not lean to either side, but that, when viewed in front, it appear perfectly upright. Sometimes standards and half-standards are, he says, seen planted a foot or two from the wall, which gives them a very disagreeable appearance: six inches is, he thinks, quite sufficient. Much care should be taken not to wound the stem or root of the tree in planting.

When young trees have two stems, he advises always to cut off one of them, leaving the stoutest and straightest, planting that side outwards which has most buds on it.

It is added, that when the buds begin to break well, the trees should be headed down to three or four eyes, to fill the wall with fine wood, but never afterward, except the leading shoot to fill the

VOL. II.

wall, leaving the fore-right shoots to be pruned, as hereafter directed. He has "had some trees that had forty pears on them the second year; while some of the same kind bore only eleven pears the fourteenth year after planting, with the common method of pruning."

When such old trees as recommended above cannot be procured, the stoutest and cleanest of the one-year's old after grafting should, he says, be provided.

Where any of these trees become stunted after a number of years, they should be headed down as hereafter directed, which will bring them into fresh vigour and fruitfulness.

The proper season for planting them out is any time in open weather from the end of October till March, but the autumn or early winter are the most advantageous periods.

They succeed well in any common garden soil, or good fertile orchard-ground, or field, that is not very wet, or of a stiff or stubborn quality, but moderately light and friable to the depth of one spade at least, and if more the better. The ground should be prepared by proper trenching one or two spades deep, as the depth of good soil will admit, wholly if for a full plantation, or only along the place for each row of trees, in the place for each tree; or only a hole for each tree at proper distances.

The proper distance for planting the dwarf sorts for walls or on espaliers, is for those on free stocks at not less than twenty feet, but if twenty-five, or more, the better, especially if the walls be rather low, &c. that there may be full scope to extend their branches considerably in a horizontal direction, as they will effectually fill that space, or even much more if it be allowed them; but they are often planted much nearer together. It is however of importance to give these trees sufficient room, and the higher the walls the better, as is evident by those trees growing against the ends of high buildings, as they extend themselves very considerably every way. Some plant cherry-trees or other moderate shooting fruit-trees in the intervals for a few years, till the pears advance in growth and approach one another, when they should be removed. They are to be planted in the usual way, with their heads entire. See PLANTING.

But for trees that are dwarfed by grafting or budding upon quince-stocks, from fifteen to eighteen feet may be a proper distance for planting, either for walls or espaliers.

In respect to the distance at which pear-trees should be planted against walls, it is observed by Mr. Forsyth that when they "are grafted on free stocks, such as Colmars, Pear D'Auche, Crasanes, L'Eschasseries, Virgouleuses,

2 S

and Winter and Summer Bonchrétiens, it should be at least twelve yards distant from each other, supposing the walls to be from twelve to sixteen feet high; but when they are only ten feet, fifteen yards will be little enough for the purpose."

Where they are planted on south walls, vines, peaches, nectarines, or apricots, may be planted between them, till the trees extend so far as nearly to meet each other: then they may be removed to any other situation in the garden where they are wanted. And where the pears are planted on west walls, the same sort of trees may be planted between them as on south walls; the fruit on a west aspect will, he says, come into use to succeed that on the south. On an east wall different sorts of plums and cherries may be planted, he says, between the pear-trees till they almost meet, then transplanted as standards or wall-trees.

He advises that the borders for pear-trees in a large garden should not be less than from ten to twenty feet wide, with a foot-path about three feet from the wall, covered over at top with coal-ashes or road-sand, to make a dry walk for getting at the trees to cut and nail them, to gather the fruit, &c. And that the depth of the mould for them should never be less than three feet, laying the best mould at top, to encourage the roots to come as near the surface as possible. If the bottom be clay, it will, he says, be very necessary, once in every five or six years, to open the ground round the roots of the trees, and cut off all the large ones that are inclining to run into the clay; as by this practice the trees will throw out fresh roots that will run near the surface, provided the mould is good near the top of the borders.

He suggests that a crop of early peas, lettuces, spinach, or any other small crops, may be grown on the borders, during the winter and spring; but no late crops by any means. If the ground can be spared, he would advise to have no summer crops, but keep the borders hoed, in particular after rain; otherwise the ground, if a strong loamy or clayey soil, will be apt to crack in dry weather; but by frequent stirring between wet and dry this will in a great measure be prevented, and the sun's rays admitted into the mould, which will greatly heighten the flavour of the fruit. When you can conveniently spare the borders in winter, they should be ridged up to sweeten the mould, which may be very well done if you sow early peas on the sides of the ridges; which is by far the best way to preserve the peas from the frost, and to prevent them from rotting, which will sometimes happen, if the land be strong, before they begin to vegetate: or, you

you may sow an early crop of carrots or spinach on these borders.

In regard to the general management in the training and pruning of these trees, if the young wall and espalier trees thus planted are only one year old from the graft or bud, having their first shoots of a year-old entire, these should in the spring be headed down to five or six inches, to force out lower horizontal branches; but if they have been previously headed, as advised above, and have thrown out laterals to form a regular set of horizontal branches, consisting of six or more near the bottom, they should not now be shortened, but trained to the wall or espalier at full length horizontally, preserving an equal number on each side five or six inches asunder: they will readily emit a further supply of horizontal shoots to cover the wall, &c. regularly upward, and at the same time not being shortened, they gradually form themselves for bearing, as every shortening of the branches of these trees retards their bearing a year at least: if, however, there is a want of branches, some of the middlemost may be pruned short, and trained to the wall or espalier. According as the trees shoot in summer, a further supply of all the regular shoots in every part where they occur, should be trained in at full length, unless it shall seem necessary to prune some strong shoots to obtain a greater supply of horizontal branches the same year, in order to furnish the head as soon as possible: at this time, however, displace all the fore-right and other irregular growths of the year, continuing the supply of regular shoots close to the wall, as they advance in length during their summer's growth. And in the winter pruning, the supply of shoots attained in summer should be well examined, selecting all those that are well placed and properly situated for training in, to increase the number of horizontal branches on each side, which should be left wholly entire, and at the same time retrenching any superfluities and ill-placed shoots omitted in summer; then the whole supply of regular horizontal branches in every part should be trained in straight and close to the wall or espalier, equally on both sides of the tree, every branch at the full length, at four, five, or six inches apart. See WALL- and ESPALIER-TREES, and PRUNING.

There is another method sometimes practised in training these trees for walls and espaliers, which is, that after their first heading down and having thrown out several laterals, to select three of the strongest and most regularly placed, one on each side and one in the middle, nailing the two side ones horizontally at full length, and the middle one upright; the tree having produced a

further supply of shoots in the following year, add two or four of them as side branches, arranging them on each side of the stem as the two former, training the middle shoot still in an upright direction; observing that where it does not furnish horizontals low enough, it may be shortened so as to make it throw out shoots at any requisite height, continuing the middle one always upward for a stem, and the side ones for bearers.

In either of these methods of training the trees, continue yearly increasing the number of horizontal shoots, till the full space of walling or espalier is regularly covered with bearers at equal distances, constantly continuing them all at full length, as far as the scope of walling, &c. will permit; as they naturally form fruit-spurs at every eye, almost their whole length, and the same branches continue in a fruitful state a great length of time.

When the trees have once filled the wall or espalier with branches, they need but very little further supply for many years, and that only occasionally, according as any worn-out or decayed branch occurs, and wants renewing with young wood. See PRUNING.

In the after-prunings in the summer, which should be begun in May, or early in June, rub off all the superfluous and unnecessary shoots of the year, and all fore-right and other ill-placed shoots, retrenching them quite close, being careful to leave the terminating shoot of every horizontal or bearer entire; and reserving here and there a well-placed shoot towards the lower parts in particular, and where there are any apparent vacancies, to train up between the mother branches, till winter pruning, when if not wanted they must be retrenched.

In the winter pruning, which may be performed any time from the fall of the leaf until March, the branches should be generally examined to see if they are any where too much crowded, or trained irregularly; and where any such occur, they should be regulated as they may require; and where there are any vacancies, some contiguous shoots, reserved in the summer dressing, should be laid in, and all the other shoots not wanted must be cut clean out close to the branches, being careful still to preserve the terminating shoot of every branch entire, in all parts, as far as the allotted space admits, likewise all the fruit-spurs in every part, fastening in all the branches regularly at full length.

In pruning old trees at this season, where decayed and worn-out branches occur, they should be cut out, and young wood trained in its stead; likewise, where any branch, through age or any

other defect, is become barren or worn out, it should be retrenched, and some eligible lower young branch or shoot be laid in in its place.

Where any of the choicer sorts of these trees are become worn-out and barren, they should be renewed with young bearers, by heading the branches wholly down near the bottom in winter or spring, when they break out in the old wood, and in the following summer furnish a large supply of strong young shoots, which should be trained according to the rules already laid down, when they will soon form a sort of new tree, and bear good fruit.

After each winter-pruning, the trees which are against walls and espaliers require a general nailing, &c., which should always be done with great regularity. See WALL-TREES, and ESPALIER-TREES.

The mode of training dwarf standard trees of this sort is shown in speaking of trees of that kind. See DWARF TREES.

In respect to the culture of the borders where this sort of wall- or espalier-trees are growing, it is commonly digging them once every year, adding manure occasionally in common with the other parts of the garden; but if some good rotten dung be applied every other year, and the ground well dug or trenched every winter, it greatly promotes the size and perfection of the fruit.

In regard to standard-trees of this kind, any of the sorts bear plentifully in any open situation, though the fruit may not always be so large and fine as those of wall- and espalier-trees: summer and autumn pears however ripen in great perfection on standards, as also most of the common winter pears. In planting them, trees of from two or three to four or five years old, having tolerable heads, are of a proper age and size for the purpose, and are preferable to older trees for any general plantation. They should be planted with all their heads entire, except retrenching any very irregular-placed branch, in the usual manner of tree-planting. See PLANTING.

In their future growth they should be suffered to branch naturally, so as to form large branchy heads, suffering them all to remain entire.

The general culture of this sort of trees, in respect to pruning, is very trifling, and only required occasionally, probably only once in several years; such as the retrenching any irregular growing branches, and thinning such branches as are very much crowded, cutting out all decayed wood, and eradicating suckers from the roots and stems. See PRUNING.

Where standard-trees are situated in a garden, in which the ground is necessarily dug over and

trenched annually for the reception of the under-crops, and occasionally enriched with dung, they generally produce finer fruit than in orchards, or other places where the ground is not in similar culture.

Mr. Forsyth observes that "the method of pruning pear-trees is very different from that practised for apple-trees in general, in which the constant practice has been to leave great spurs as big as a man's arm, standing out from the walls from one foot to eighteen inches and upwards." The constant pruning, he says, "inevitably brings on the canker; and, by the spurs standing out so far from the wall, the blossom and fruit are liable to be much injured by the frost and blighting winds, and thus the sap will not have a free circulation all over the tree. The sap will always find its way first to the extremities of the shoots; and the spurs will only receive it in a small proportion, as it returns from the ends of the branches; and the fruit standing at so great a distance from the wall is too much exposed to the weather, and, of course, is liable to be hard, spotted and kernelly."

The following method, he says, he has practised where the trees were all over cankered, and the fruit small, and not fit to be sent to the table. "He cut the tops off as near as possible to where they were grafted, always observing to cut as close to a joint or bud as possible. The buds are hardly perceptible, but it can always, he says, be known where the joints, or forks, are, by the branches breaking out of the sides."

He adds, that "finding the pear-trees in Kensington Gardens in a very cankered and unfruitful state, in the years 1784 and 5, he took out the old mould from the borders against the walls, and put in fresh loam in its stead; at the same time he pruned and nailed the trees in the common way, and left them in that state upwards of eighteen months, to see what effect the fresh mould would have on them; but, to his great surprise, he found that it had no good effect."

After this trial he began to consider what should be done in order to recover these old trees. In this attempt he "began with cutting down four old and decayed pear-trees of different kinds, near to the place where they had been grafted: this operation was performed on the 15th of May, 1786. Finding that they put forth fine shoots, he headed down four more on the 20th of June in the same year (for by this time the former had shoots of a foot long), which did equally well, and bore some fruit in the following year. One of the first four that he headed down was a St. Germain, which produced nineteen fine large well-flavoured pears next year, and in the third bore more fruit than it did in its former

state when it was four times the size. He left seven trees upon an east wall, treated according to the common method of pruning, which bore the following number of pears upon each tree: Epine d'Hyver produced eighty-six pears, and the tree spread fifteen yards; a Crasane produced one hundred pears, and the tree spread fourteen yards; another Crasane produced sixteen pears, and the tree spread ten yards; a Virgouleuse produced one hundred and fifty pears, and the tree spread nine yards; a Colmar produced one hundred and fifty pears, and the tree spread nine yards; another Colmar produced seventy nine pears, and the tree spread ten yards; a L'Eschasserie produced sixty pears.

"But seven trees headed down and pruned according to his own method, leaving the fore-right shoots in summer, bore, he says, as follows, in the fourth year after heading:—a Louisbonne bore four hundred and sixty-three pears, and the tree spread nine yards; another Louisbonne bore three hundred and ninety-one pears, and spread eight yards; a Colmar bore two hundred and thirteen pears, and spread six yards; a Brown Beurré bore five hundred and three pears; another Brown Beurré bore five hundred and fifty pears; a Crasane bore five hundred and twenty pears; a Virgouleuse bore five hundred and eighty pears. And he adds that the branches of the four last trees spread nearly in the same proportion as the first three. He also states that a young Beurré, the second year after heading, bore two hundred and thirty pears; and a St. Germain four hundred. All the above trees stood in the same aspect and the same wall, and the fruit was numbered in the same year. A great many pears which dropped from the trees are not reckoned. The trees that were pruned according to the old practice covered at least one-third more wall than the other.

From this statement it appears, he says, that the trees headed down bore upwards of five times the quantity of fruit that the others did; and that it keeps increasing in proportion to the progress of the trees. This is an important statement in the culture and management of old trees of this sort; and the following fact with respect to standards is deserving of great attention:—

"On the 20th of June he headed several standards that were almost destroyed by the canker; some of them were so loaded with fruit the following year, that he was obliged to prop the branches, to prevent their being broken down by the weight of it. In the fourth year after these standards were headed down, one of them bore two thousand eight hundred and forty pears. There were three standards on the same

border with the above, two of which were St. Germain's; the old tree was of the same kind. One of these trees, twenty years old, had five hundred pears on it, which was a great crop for its size: so that there were on the old tree, which had been headed down not quite four years, two thousand three hundred and forty pears more than on the tree of twenty years growth. When the men numbered the pears, there was, he says, near a barrowful of wind-falls at the bottom of the old tree, which were not included.

These and other statements are given in his useful *Treatise on the Culture of Fruit-Trees*.

The following is the method which he pursues in training trees that are cut near to the place where they were grafted:—

“In the month of March, every year, he shortens the leading shoot to a foot or eighteen inches, according to its strength: this shoot will, he says, if the tree be strong, grow from five to seven feet long in one season; and, if left to nature, would run up without throwing out side-shoots. The reason for thus shortening the leading shoot is, he says, to make it throw out side-shoots; and if it be done close to a bud, it will frequently cover the cut in one season, leaving only a cicatrix. When the shoots are very strong, he cuts the leading ones twice in one season; by this method he gets two sets of side-shoots in one year, which enable him the sooner to cover the wall. The first cutting is performed any time during the spring, and the second about the middle of June. When you prune the trees, and cut the foreright shoots, which should be done in February or March, always cut close to an eye or bud, observing where you see the greatest number of leaves at the lower bud, and cut at them; for at the footstalk of every one of these will be produced a flower-bud. The same will hold good in cutting the superfluous shoots on standard pears.” He adds, that “you will have in some sorts of pears, in a favourable season, from five to nine pears in a cluster. This cutting should not be later than March, or the beginning of April, on account of the leading shoot beginning to grow: the next topping, when the leading shoot grows quick enough to admit of it, should be about the middle of June; and the length of the shoots should be according to their strength, having from three eyes, or buds, to fix on a side.”

It is added that “the canker part beginning to affect the new bark, he cut off all the canker at the bottom, and plastered the place with some cow-dung, mixed with wood-ashes and powder of burnt bones, put into as much urine and soapsuds as would make it of the consistence of

thick paint; this he laid on with a painter's brush. After it had been applied about three hours, he patted it gently down, with his hand, close to the tree. By so doing, he gets rid, he says, of all the air-bubbles that may be under the Composition, and makes it adhere to the tree, preventing it from being washed off by heavy rains. And in the beginning of August he shortens the foreright shoots to about four inches long; by this time the shoot will have made its full growth for the season, and will produce fine strong eyes for the following year. Such shoots as grow near the stem of the tree, if any are wanted to fill up the wall, may, he says, be tucked-in as directed for peaches. This will prevent them from looking unsightly, and save them from the fury of the autumnal and winter winds.”

He further advises, that “whenever the trunk is hollow, it be followed under ground till you have cut out all the decayed parts and rotten roots, otherwise you will lose the tree. By proceeding according to the foregoing directions, the root will, he says, be renewed, while the tree is forming a fine handsome head. In the mean-time the borders should be trenched, taking up all the old roots, and adding some fresh mould to them, if you can conveniently get it; if you cannot, remove all the sour mould that is about the roots of the trees, and put in some taken from the border, at a distance from the wall; always remembering to lay the top spit next to the roots of the trees; also, to mix some vegetable mould, from the melon and cucumber beds, with rotten leaves, as a manure for the borders.”

He has “headed down, he says, many trees that had not this preparation; and yet they thrived very well, but did not send forth such fine roots and shoots as those that were so prepared.”

He concludes by observing, that “if the above directions be followed, more pears will be procured in three or four years than can be done in twenty-five years by planting young trees, and pruning and managing them in the common way. It is added, that if it should be found, that, before the pears arrive at half their natural size, they get stunted, after cold blighting winds, and frosty nights, he would recommend a new operation to be performed when the weather begins to grow mild, which is to take a sharp penknife, and with the point of it make an incision through the rind of the pear from the footstalk to the eye, in the same way as in scarifying a bark-bound tree, taking care to penetrate as little into the flesh of the pear as possible. At the same time beat up some fresh

cow-dung with wood-ashes, and with your forefinger rub in a little of this Composition where you made the scarification; as the wound heals, the Composition will be discharged from the fruit; this will prevent the pears from cracking and bursting, which renders them good for nothing. The sorts that are most liable to this disorder are, he observes, the Colmar, Virgoultense, and Crasane. He only, however, recommends this operation for wall pears, as it may be thought by some a troublesome operation, and it will certainly take up some time."

The maturity of the pear is generally known by its changing from a green to a yellow or reddish colour, &c., and by the frequent falling from the tree, and when with a gentle twist or turn upwards, it easily quits its hold; but these signs of ripeness are more particularly observable in Summer and Autumn pears; as Winter pears not being maturely ripe when gathered, often require a good pull before they quit the branches.

The Summer pears ripen in succession in different sorts, from about the beginning or middle of July till the middle of September; many of the earliest ripening all at once, as it were, and continuing good but a few days, either on the tree or when gathered, nor will any of the sorts keep good long; and none of these sorts should hang on the tree till soft ripe, as in that case most of them would be mealy and insipid. These sorts should be gathered as soon as they are arrived to full growth, and just begin to colour and discover maturity, but before they become soft and mellow. For family use, they may be gathered from the tree according as they attain perfection; but the general crops of each sort should be always taken down before they ripen fully, and be laid in any dry room; none of the kinds will keep long, some only a few days, and scarcely any of them above a fortnight, though from different varieties ripening at different times, the succession is continued for eight or ten weeks.

The Autumn sorts ripen in different varieties, from about the middle of September till the end of October; some of the forwardest become eatable on the tree, others requiring to lie some time after being gathered before they acquire perfection. The different sorts of these pears should be gathered according as they arrive to maturity: those designed to keep some time, may be gathered in dry weather, just when they have attained full growth, as shown by their frequent dropping, and by their readily quitting the trees on being handled, and laid in a dry close room, or in baskets, each sort separately.

The Winter kinds attain their full growth on the trees about the end of October or beginning

of November; but the eatable kinds do not acquire maturity for that purpose on the tree, or for some considerable time after they are gathered, some probably in a month, others two or three, and some more, and some sorts not till the spring following. But the baking kinds may be used any time from October or November during their continuance.

All Winter pears should be indulged with as full growth on the tree as the weather will permit, even until the end of October or first week in November in the later kinds, if the season continues mild: be cautious, however, to get them gathered before attacked by much frost. And in gathering all the sorts for keeping, dry weather should be chosen, and when the fruit is also quite dry, being careful not to bruise them. See FRUIT.

Forcing of Pears.—These sorts of trees are sometimes forced by artificial heat, in some of the prime early summer kinds, to obtain a portion of fruit as early in the season as possible. This is effected by means of hot-walls and forcing frames; having previously some trees of the choicest early summer pears, such as the Jargonelle, or any other early sort, trained as wall-trees against a south wall, till advanced to some tolerable state of bearing; being then inclosed with glass frames, in the manner of forcing-frames or hot-walls, and having internally either flues for fire heat, erected forward and extending long-ways, or otherwise a pit arranged in that direction, in the interval space between the trees and the glass-work, for a bark or dung hot-bed; and by one or other of these methods a proper degree of artificial heat is produced internally to force an early growth in the trees, and forward them to early flowering and fruiting, managing them in the common way, as other trees in forcing-frames, so as to have some ripe fruit early in June, or some time in that month.

Culture in the Apple Kind.—The whole of the varieties of the apple were first accidentally obtained by raising them from the kernels of the fruit; but as these cannot be depended upon to continue the same sort of fruit, grafting is the mode made use of to increase and continue the different varieties of them, which is performed upon Crab, or any kind of Apple stocks, raised from the kernels, for dwarfs as well as standards: and sometimes upon Codlin and Paradise Apple stocks raised from cuttings and layers, when designed to have espaliers and other dwarf trees, or for small standards, as low as possible, to be confined within a moderate space: some sorts may also be raised by layers and cuttings, as the common Codlin,

The method of raising the different sorts of stocks for the purpose is, in the Crab and Apple stocks from the kernels of the fruit; but in the Codlin and Paradise stocks by cuttings and layers, to continue them with certainty of the same kinds and moderate growths. The Crab and Apple stocks may be raised from the kernels of any of the sorts, procuring them in autumn or winter, either from the fruit, or from such as have been pressed for verjuice and cider, clearing them from the grossest of the pulp; then sowing them in beds of light earth, moderately thick, over the bed, or in drills, covering them about an inch deep. They come up in the spring; when, if the season prove dry, they should be watered occasionally, to forward and strengthen the growth of the plants; and in the autumn, winter, or spring following, the largest may be planted out in nursery-rows, shortening their tap-roots a little, and placing them in lines two feet and a half asunder, to remain for grafting: after having from one to two or three years' growth, they will be fit for grafting upon, particularly for dwarfs, or even for full and half standards, if intended to form the stem from the graft, which is an eligible method for these trees; but if the stock is to form the stem, they require three or four years' growth, to rise to a proper height, seven feet for full, and four or five for half standards. The modes of grafting all the sorts is the same as for other fruit-trees, and should be performed in March, either by whip- or cleft-grafting, according to the size of the stock. See **GRAFTING**.

Having provided proper grafts of the different sorts of apples intended to be raised, the stocks designed for dwarfs of all sorts must be grafted within six inches of the ground; and the standards may also be grafted low, one shoot from the graft being trained up for a stem, or on tall stocks, at five or six feet in height, but for low and half standards, at two or three, to four or five feet, and lower for dwarf standards. The grafts of all the sorts shoot the same year; and by the autumn following, the trees having formed little heads, consisting of two, three or four shoots, may then be planted out finally where they are to remain, or be retained a year or two, or longer, in the nursery, as may be requisite, training them for the purposes intended, as dwarfs, espaliers, &c., &c., and uprights for standards, heading the dwarfs down in March following, within six inches of the graft, to force out more lateral shoots below to form a fuller head, proceeding immediately to turn them near the bottom, so as to fill the espalier, &c., equally with branches, quite from within six or eight inches of the ground, regularly upward. In

the standards, those grafted low must be trained with one shoot upright, at full length, for a stem, five or six feet high at least, for full standards, before it is topped; though if grafted on tall stocks of height sufficient for a stem, the shoots from the graft may either be headed to five or six eyes; or, if to form a more spreading head, remain entire, and aspire more in height, and assume a more upright growth: in all the modes of training, care should be taken to keep the stems clear from all lateral shoots, displacing all such as soon as they appear, encouraging only a proper set of branches at top to form the head.

When these trees have heads from one to two or three years old from the graft, they are of a proper age for final planting out; though trees of four or five years old will also succeed very well, and even those of six or eight years' growth may also be safely planted if required.

The nursery-grounds are mostly furnished with all the varieties of these trees for sale, either quite young from the graft, or trained of several years' growth.

In choosing the different kinds of trees for planting, care should be taken to have a collection of the principal varieties, both in espaliers and standards, in proportion to the extent of ground, as the trees of the best sorts are as easily raised and cultivated as the indifferent ones, allotting a smaller portion of the summer kinds, as such as ripen from August to about the middle of September, for immediate use off the trees, as they will not keep long; a larger supply of the autumn sorts, and most of all of the principal winter keeping apples: observing, in the summer kinds, that it is advisable to allot a principal supply of the common Codlin in small standards, as being generally both a great bearer, and the fruit the most useful of the summer apples for culinary purposes, from its young green growth in June or July, till its full maturity in August and September, when it becomes also a good eating apple: and as the tree is a moderate grower, it admits of being planted in small standards closer or more abundant in a small extent of ground than most of the principal apple kinds.

In choosing apple-trees from the nursery, they should, Mr. Forsyth says, have strong, straight, and clean stems. And he advises not to suffer the dwarf-trees to run higher than twelve feet, as otherwise they become naked at bottom, the fruit is liable to be blown down, and the tops broken by high winds.

The proper season for planting all the sorts of apples is in mild weather, from the end of October till March; but when planted in autumn,

or early in winter, they establish themselves more firmly before the drought of the following summer.

They succeed in any common soil and open situation, except in low very moist land, in which they are apt to canker, and soon go off: in a pliable mellow loam they generally answer very well. The ground should be properly prepared, by good trenching, where the ranges of trees are to stand.

In the planting of Espalier Apple-trees they should be ranged at not less than eighteen or twenty feet distance; the latter especially for trees grafted on Crab or Apple stocks, which being free shooters, the branches readily fill that space. For the trees grafted on Codlin and Paradise stocks, fifteen or eighteen feet may be sufficient; though the latter, in particular, is sometimes planted only twelve or fifteen feet asunder, as being a very moderate shooter: it is, however, advisable to allow every sort full room, according to their growth, to have proper space to extend their branches always at full length. The trees should be planted with all their heads entire, only retrenching any very irregular growths, that do not range consistently with the intended form, and pruning any broken roots. Then having opened a proper hole for each tree, plant them in the usual manner, being careful to place them with their branches ranging the way of the espalier. As soon as the earth of the holes and of the roots is properly settled, all the branches should be trained in horizontally to the right and left, an equal number on each side, at full length, as above.

The general culture in espalier trees thus planted and trained, as the same branches or bearers continue fruitful many years, is to continue them as long as they remain of proper growths, constantly giving them a summer and winter pruning annually, as explained above.

In wall-trees also, any of the principal choice varieties of eating-apples may be trained, to forward and improve the growth, beauty, and flavour of the fruit; such as Jennetings, Margaret-apple, Golden-pippins, Golden-remnets, Pear-mains, &c., or any other approved eating kinds, a tree or two of a sort, against a south or south-west or east wall.

Standard apples when planted in the garden should be arranged thinly, to admit of under-crops growing freely, without being shaded by their spreading branches.

Full standards should be chiefly planted for the general crops, and half and dwarf standards for variety.

The standards, when trained as above, should be planted out with all their heads entire, when

in the kitchen garden, at thirty feet distance in the rows; and for an orchard thirty feet distance every way. In planting, for each tree a wide hole should be opened, trimming any long straggling and broken roots, leaving all the others entire, and planting them with the usual care. As soon as planted out, every tree should be well staked to support them firmly upright, and prevent their being disturbed in rooting by winds. See ORCHARD and PLANTING.

Smaller growing standards, such as Codlins, or other low standards grafted upon Codlin stocks, and dwarfs upon these or Paradise stocks, may, if required, be planted only at fifteen or twenty feet distance in the rows, and not less than twenty or twenty-five feet between the lines of trees; though, if there be room to allow a greater distance both ways, it will be advantageous, especially in planting in kitchen gardens, in which it would be proper to allow double that distance between the rows of trees, of the larger growths of these kinds.

The standards thus planted with their heads entire, should be suffered to advance with their branches at full length, and in general take their natural growth, when they soon form numerous natural spurs in every part for bearing.

In respect to pruning these standards, little is required, only the occasional retrenching any very irregular cross-placed bough, or the reducing to order any very long rambler; or when the head is become greatly crowded and confused, to thin out some of the most irregular growths, likewise all strong shoots growing upright in the middle of the head, and all dead wood, and suckers from the stem and root.

As to half and dwarf standards of these trees, they may be dispersed in different parts of the garden to cause variety, managing them as the full standards.

The former on dwarf Paradise stocks, being very moderate shooters, may be planted in a little compass; and are sometimes planted in pots for curiosity, to place on a table, amidst a dessert, with the fruit growing on them. See DWARF TREES.

It is observed by Mr. Forsyth, that "in heading down old decayed apple-trees, for the sake of symmetry, it will be necessary to cut at the forked branch as near as can be to the upper side of the fork, cutting them in a sloping manner to carry off the wet, at the same time rounding the edges. To begin at the lower branches, cutting just above the lower fork; and proceeding upwards, cutting the rest of the branches from one to six joints, or forks, according to their strength, till you have finished cutting-in the whole head. If any of these branches should have the canker,

all the infected part must, he says, be cut out. When the tree is all prepared, the Composition should be immediately applied, beginning at the top of the tree, and finishing with the powder of wood-ashes and burnt bones as you descend, which will save it from being rubbed off during the operation; and the Composition will prevent the sun and air from injuring the naked inner bark. A tree thus prepared, will, he adds, in the course of three or four years, produce more and finer fruit than a maiden tree that has been planted upwards of twenty years."

These directions, if properly attended to, will be sufficient, he thinks, to enable any one to bring old decayed trees into a healthy bearing state.

He supposes, that in large orchards and gardens, it may be necessary, at first, to head down only every other tree; cutting some of the branches of the rest, which are in a decayed and cankerous state, and which bear no fruit. This will, he says, be preparing them to throw out new wood, and furnish the tree much sooner with bearing branches. He recommends the performing the operation as early as possible; as by so doing the wood will be the stronger, as in May, or the two following months.

He adds, that when the trees are become hollow, the same method should be followed as directed for plums; but by no means to cut them down unless the tops are quite decayed; observing to cut the loose rotten wood clean out of the hollow and other decayed parts, applying the Composition; at the same time to open the ground, and cut out all the rotten parts that may be found in the lower part of the stem, together with all the decayed roots, which, if this be not done, will infallibly injure the fresh wood and bark, and prevent a cure from being effected. He would recommend heading down all apple-trees that are much cankered and have ill-shaped heads; as by so doing much labour will be saved, and the trees will amply pay the proprietor. He advises never to shorten the young branches, except they are very thin, when it will be necessary to do so to fill the trees with young wood: nor prune any of the young shoots the second year (he means the year after they are cut), as many of the eyes, almost to the end of the shoot, will, if it be strong, become fruit-buds next year; and so on every year. He says, that in the month of May in the first year after the trees have been so cut, it will be necessary to go over them, and rub off with your finger and thumb all the superfluous young shoots; leaving from three to six eyes on each shoot, according to the size and strength of the branch cut. These shoots will bear from three to four years; by which time they will be pretty much exhaust-

VOL. II.

ed by the great quantity of fruit produced from them: they should then be cut down to two eyes to produce new wood. He always leaves three different years' branches on the tree, when the first shoot is cut off. This is fully shown in a plate in his useful work; and the next shoot will be full of fruit-buds, if it has not been shortened: when it begins to grow weak, it should be cut off; and the next cutting must be made when the former branch is tired of bearing: by proceeding thus all over the tree with care and attention, the advantages of this method of pruning, above the common mode, will, he says, soon be perceived; as by it you will be able to keep the trees in a constant state of bearing, which, if left to nature, would only produce a crop of fruit once in two or three years. When the shoot that has done bearing is cut off, the Composition should constantly be applied, rubbing off the shoots where they are too numerous.

He thinks the best time to prune apple-trees is in the month of April, or in May, after the operation has been performed on the peaches, nectarines, and cherries: and that soon after this pruning, about the middle of May, it will be proper to look over the trees, and to pick off any caterpillars that may be on them. It will then be seen what shoots are infected with the canker, and which might have escaped your notice at the time of pruning; and wherever you observe the least appearance of infection, which may be known by the wood appearing of a brownish colour, the shoot must be cut down till you come to the sound white wood.

The small shoots that cross each other should be cut off, leaving the strongest to fill up the tree, and make a fine handsome head. The suckers that spring from the root should be carefully grubbed up, and the side-shoots from the stem cut off; for, if left to grow, they greatly weaken the tree. The knobs, where old branches have been cut off, should also be pared away, leaving the surface of the tree as smooth as possible: after which, the Composition should be applied: the young bark will soon, he says, begin to grow, and by degrees cover the old wounds with a fresh smooth surface, and thus prevent the canker from gaining ground on the tree. He has seen some old wounds of considerable size healed over in one year: and he adds, in confirmation of the utility of this practice, that "the trees which he pruned and dressed, as above directed, in the course of the summer, 1795, are all perfectly cured, the wounds being filled up with sound wood, and covered over with new bark: they all continue in a healthy state, and bear fine handsome fruit." And he has advised several nurserymen to follow the practice, head-

ing down their apple-trees after the season of drawing for sale is over. Messrs. Gray and Wear have headed a great many of such trees as were formerly thrown to the faggot-pile, and have been amply recompensed for their trouble. Trees thus headed down, provided the stems be strong, will, he thinks, in the first and second year, produce as much fruit as will refund the purchase-money; besides, a great deal of time will be saved, which would be lost by planting younger trees: as, where you can procure trees of the above description that have been headed down three or more years, they will be all covered with fruit-buds; and, if carefully taken up and planted in the autumn, if the season proves favourable, they will have a tolerable crop of fruit the first year. Such trees must not be headed down like maiden-trees, but only thinned off where the branches run across and rub against one another, which should never be suffered in these cases.

He says, he would never recommend training apple-trees as espaliers; as by doing so the air is kept from the quarters of the garden; and by constant pruning and cutting off all the side-shoots which you cannot tie to the espaliers, you prevent them from bearing, and, moreover, bring on the canker.

And when the dwarf trees have handsome heads, more and much finer fruit will be gotten; he says, from one of them than from six espaliers; at the same time, a free air is admitted to the crops in the quarters, and the constant expense of stakes and labour, in laying the trees to the espaliers is saved. Espaliers may, he observes, be converted into dwarf standards by shortening the branches at different lengths, so as that they may be able to support themselves without the stakes; but not to shorten them all regularly; and if cut with judgment, as near to a leading shoot, or an eye, as possible, they will in the course of two years form fine heads, and in the third year bear six times as much fruit as they did in their former state, and of a finer flavour. The same method of pruning as already laid down for standard apple-trees is also applicable to espaliers.

He observes, that "the borders where you make your crossings in gardens should be six or eight feet broad at least, to let the trees spread on each side, at the distance of twelve feet from tree to tree, and they should be well trenched, two feet and a half deep at least. If there should be gravel, or sour clay, it must be taken out, and good mould put in its place; leaving the ground as rough as possible for the frost and rain to mellow it. When you level the ground it should be done after rain: you may then sow

some small crops in the borders; such as lettuce or spinach, or cabbage for transplanting; but let not any of the Brassica tribe come to full growth. Leaving cabbage and brocoli on borders, near fruit-trees, draws the ground very much, fills the borders with insects, and also prevents the sun and air from penetrating into the ground. And when the sun can have free access to the border, it adds much to the flavour of the fruit. If you can spare the ground on the cross-borders in winter, it will be of great service to the trees to ridge it up as loose as you can, and let it lie in that state all winter, to mellow and sweeten.

Where the soil is strong, he would recommend planting of apple-trees that are grafted on Paradise stocks; but if the soil be light, free stocks will do much better; and when the ground is a strong clay or brick-earth, it should be mixed with old lime-rubbish or coal-ashes, street-dung, or sand: but what he uses for the borders against the walls, and which he prefers to every other manure, is a vegetable mould produced from leaves of trees.

Of this a good coat should be given once in two or three years, which will be sufficient, he thinks, for the borders where the wall-trees stand, and much better than dung, which he by no means approves of for trees, unless it be perfectly rotten and mixed up with mould.

In respect to grafting old apple-trees, he says, "it frequently happens, that, through some mistake or other, after waiting ten or twelve years for a tree to come into a bearing state, it is found that the fruit is neither fit for the table nor kitchen; in such cases they should always be grafted the following spring, observing to graft on the finest and healthiest shoots, and as near as possible to the old graft, and where the cross-shoots break out; as by so doing you will have some fruit the second year; and in the third, if properly managed, you will have as much as on a maiden-tree of fifteen years standing: the canker, if any, must be carefully pared off the branch, and the scion must be taken from a sound healthy tree. Whenever an incision is made for budding or grafting, from that moment the canker, he says, begins. He would, therefore, recommend to those employed in budding or grafting, as soon as the incision is made, and the bud or graft inserted, to rub in with the finger, or a brush, some of the Composition before the bass is tied on; then to cover the bass all over with the Composition as thick as it can be laid on with a brush, working it well in. If this operation be performed in a proper manner, and in a moist season, it will answer every purpose, he says, without applying any grafting-clay: as he has frequently done it, and found it

succeed perfectly to his wishes. The matting which is wrapped round the bud should not be slackened too soon; for in that case you will find the incision opened, which very often occasions the death of the bud. If, says he, nurserymen and gardeners would give this method a fair trial, and use the same composition as he uses for curing defects in trees, instead of loam and horse dung (which bind so hard as to prevent the rain and moisture from penetrating to the graft to moisten the wood and bark), they would find that the grafts would succeed much better. The composition, for this purpose, should, he says, be rather softer than grafting-clay generally is; and, instead of applying so large a mass as is generally done of clay, it need not, in most cases, be more than two or three inches in circumference, to effect the purpose.

Apples come to full growth in different sorts successively, from July until the end of October: the summer kinds continue but a short time, but the autumn- and winter-apples keep from two or three to six or eight months, in different varieties. The signs of perfection or full growth of the different sorts of apples, are by their assuming a lively colour, emitting a fragrant odour, frequently falling from the tree, and by quitting their hold easily on being handled.

In the gathering of all the sorts of apples for keeping, dry weather should always be chosen, and when the trees and fruit are also perfectly dry: observe likewise in gathering apples for the table, and all kinds of apples designed for keeping any considerable time, that they be pulled one and one by hand. See **FRUIT**.

The other species may be increased by grafting and budding them upon the common Crab stock: they should have sheltered situations, as they are rather tender while young. These trees afford ornament and variety in the clumps and shrubby parts of pleasure-grounds.

Culture in the Quince Kind.—These trees may be raised from the kernels of the fruit sown in autumn; but there is no depending on having the same sort of good fruit from seedlings, nor will they soon become bearers. But the several varieties may be continued the same by cuttings and layers; also by suckers from such trees as grow upon their own roots, and likewise be increased by grafting and budding upon their own or Pear-stocks raised from the kernels in the same manner as for apples.

The raising by cuttings, layers, and suckers is performed in autumn, winter, or spring, choosing young wood for the cuttings and layers, which should be planted and laid in the common method, when they will be rooted by the following autumn, then planted out into nursery rows two feet asunder; plant the suckers also at the same

distance, and there training the whole for the purposes intended: if for standards, run them up with a stem to any desired height, from three to five or six feet, then encourage them to branch out at top, to form a head; and those designed as dwarfs must be headed near the ground, and trained accordingly for espaliers, or dwarf standards, as directed under those articles: the grafting or budding is effected on Quince- or Pear-stocks, and trained as above.

When they have formed tolerable heads, they should be planted out finally.

Mr. Forsyth advises that the layers or cuttings should be planted in a shady place, in rows at about a foot distant from each other, and about three inches from plant to plant in the rows; mulching them with rotten leaves, or rotten dung, which will keep the ground about them moist; and watering them frequently in hot weather. About Michaelmas those that are well rooted may be planted out, and those that are not should remain another year. They may also be propagated by budding or grafting; and these trees will bear sooner, and be more fruitful than those raised by any other method.

He observes, that the quince-tree may be pruned much in the same way as an apple-tree, taking care to cut out all the old diseased and dead wood, and the cross branches in the middle of the tree, which are apt to injure each other by friction. In general you will find old trees much hurt by injudicious pruning: in that case they should be headed down, cutting out all the canker parts, and also all the diseased and dead wood where the tree is hollow, or where large branches have been cut or broken off; applying the composition as for apple-trees: and as quince-trees are very apt to have rough bark, and to be bark-bound, in these cases it will be necessary to shave off the rough bark with a draw-knife, and to scarify them when bark-bound, brushing them over with the composition.

It is also advised to plant quince-trees at a proper distance from apples and pears, as bees and the wind may mix the farina, and occasion the apples or pears to degenerate.

Standard quinces, designed as fruit-trees, may be stationed in the garden or orchard, and some by the sides of any water, pond, watery-ditch, &c. as they delight in moisture, suffering the whole to take their own natural growth: and as espaliers, they may be arranged in assemblage with other moderate-growing trees, such as apples and pears on paradise and quince-stocks, cherries, &c. being trained as directed for apples and pears in espaliers. They may also be planted in shrubberies either as full or low standards, and permitted to take their own way of growth. See **ORCHARD**.

QUEEN'S GILLIFLOWERS. See HESPERIS.

QUERCUS, a genus furnishing plants of the forest deciduous evergreen ornamental tree-kinds.

It belongs to the class and order *Monoecia Polyandria*, (*Enneandria Monogynia*, *Octandria Tetragynia*), and ranks in the natural order of *Amentaceae*.

The characters are: that in the male flowers the calyx is a filiform ament, long, loose: perianth one-leaved, subquincifid: segments acute, often bifid: there is no corolla: the stamens have from five to ten filaments, very short: anthers large, twin; females sessile in the bud, on the same plant with the males: the calyx is an involucre, consisting of very many imbricate scales, united at the base into coriaceous hemispherical little cups; the outer ones larger, one-flowered; permanent: perianth very small, superior, six-cleft, permanent: segments acute, surrounding the base of the style, pressed close: there is no corolla: the pistillum is a very small germ, ovate, inferior, three-celled: rudiments of the seeds double: style simple, short, thicker at the base: stigmas three, reflex: there is no pericarpium: the seed is a nut (acorn) ovate-cylindrical, coriaceous, smooth, filed at the base, one-celled, fixed in a short hemispherical cup tubercled on the outside.

The species cultivated are:—1. *Q. Robur*, Common Oak Tree; 2. *Q. Phellos*, Willow-leaved Oak Tree; 3. *Q. Prinus*, Chestnut-leaved Oak Tree; 4. *Q. nigra*, Black Oak Tree; 5. *Q. rubra*, Red Oak Tree; 6. *Q. alba*, White Oak Tree; 7. *Q. esculus*, Italian or Small Prickly-cupped Oak Tree; 8. *Q. Aegilops*, Great Prickly-cupped Oak Tree; 9. *Q. Cerris*, Turkey Oak Tree; 10. *Q. Ilex*, Evergreen or Holm Oak Tree; 11. *Q. Gramuntia*, Holly-leaved Evergreen Oak Tree; 12. *Q. Suber*, Cork-barked Oak, or Cork Tree; 13. *Q. coccifera*, Kermes Oak Tree.

The first is well known, and attains a very great size, but slowly. In woods it rises to a very considerable height, but singly it is rather a spreading tree, sending off horizontally immense branches, which divide and subdivide very much. The trunk is covered with a very rugged brown bark. The leaves alternate, oblong, blunt, and broader towards the end; the edges deeply sinuate, forming obtuse or rounded lobes, dark green and shining above, paler underneath and finely netted, five inches or more in length, two and a half in breadth: they are deciduous, but often remain on the tree till the new buds are ready to burst. A native of Europe.

There are several varieties; as with the acorns on long peduncles. This is found in the wilds

of Kent and Sussex, where there are many large trees. The leaves are not so deeply sinuated, nor are they so irregular, but the indentures are opposite; they have scarce any footstalks, but sit close to the branches: but the acorns stand upon very long footstalks. The timber of this sort is accounted better than that of the common oak, and the trees have a better appearance.

The Broad-leaved Evergreen Oak, which grows upon the Apennines, and also in Suabia and Portugal. The leaves are broader and not so deeply sinuated as those of the common oak; they are of a lighter green on their upper side, and pale on their under, have very short footstalks, and their points are obtuse; the acorns have very long footstalks, which frequently sustain three or four in a cluster.

The Dwarf Oak, which grows in the South of France and Italy, and is a low bushy oak, rises but six or seven feet high, sending out many slender branches the whole length. The leaves are oblong and obtusely indented, about three inches long, and an inch and half broad, standing upon slender footstalks; the acorns small, growing in clusters.

There are also many other varieties of common oak which dealers in timber and woodmen distinguish by their use, qualities, and accidents, and to which they give different names; but these being merely local, and not founded on permanent characters, it is difficult to ascertain them.

The second species grows naturally in North America, flowering in May and June. There they distinguish two sorts, one of which is called The Highland Willow Oak, and grows upon poor dry land; the leaves are of a pale green and entire, shaped like those of the willow tree. The acorns are very small, but have pretty large cups.

The other grows in low moist land, and rises to a much greater height: the leaves are larger and narrower, but the acorns are of the same size and shape. It is suggested, as probable, that their difference may be owing to the soil in which they grow. Martyn observes, that the latter becomes a large timber tree, and that there are said to be several varieties of it.

The third species has seemingly two varieties, one of which grows to a much larger tree than the other; but this may be occasioned by the soil, for the largest trees grow in rich low lands, where they become bigger than any of the North American Oaks. The wood is not of a very fine grain, but is very serviceable; the bark is gray and scaly; the leaves are five or six inches long, and two inches and a half broad in the middle, indented on the edges with many transverse veins running from the midrib to the

borders; they are of a bright green, and so nearly resemble those of the chestnut-tree as scarcely to be distinguished from it. The acorns are very large, and their cups are short. The leaves of the other variety are not so large, nor so strongly veined, and the acorns are smaller and a little longer. The different varieties are distinguished by the form of the leaves, which in the one is ovate and in the other oblong. It flowers here in May and June.

The fourth species grows on poor land in most parts of North America, where it never attains to a large size, and the wood is of little value. The bark is of a dark brown colour. The leaves are very broad at the top, where they have two waved indentures, which divide them almost into three lobes; they diminish gradually to their base, where they are narrow; they are smooth, of a lucid green, and have short footstalks. The acorns are smaller than those of the common oak, and have short cups.

The fifth arrives at a large size in North America, where it grows naturally. The bark is smooth, of a grayish colour, but that of the younger branches is darker. The leaves six inches long, two inches and a half broad in the middle, obtusely sinuate, each sinus ending in a bristly point, bright green, standing upon short footstalks: the leaves continue their verdure very late in autumn; so that unless hard frost comes on early, they do not fall till near Christmas, and do not even change their colour much sooner. The acorns are a little longer than those of the common oak, but not so thick. There are several varieties.

The sixth species is esteemed preferable in America to any of their other sorts for building, being much the most durable. The bark is grayish; the leaves are light green, six or seven inches long, and four broad; they are regularly cut almost to the midrib, and stand on short footstalks. The acorns greatly resemble those of the common Oak.

The seventh has the leaves smooth and deeply sinuated; some of the sinuses are obtuse, and others end in acute points; they are on very short footstalks: the branches are covered with a purplish bark when young: the acorns are long and slender; the cups rough and a little prickly, sitting close to the branches. These acorns are sweet, and frequently eaten by the poor in the South of France: in times of scarcity they grind them and make bread with the flour. It is a native of the South of Europe, flowering in May.

The eighth species is one of the fairest species of oak. The trunk rises as high as that of the common oak; the branches extend very wide on every side, and are covered with a grayish bark,

intermixed with brown spots. The leaves are about three inches long, and almost two inches broad, deeply cut with most of the teeth turning back, and terminating in acute points; they are stiff, of a pale green on their upper side, and downy on their under. The acorns have very large scaly cups, which almost cover them; the scales are woody and pointed, standing out a quarter of an inch; some of the cups are as large as middling apples. A native of the Levant, whence the acorns are annually brought to Europe for dyeing.

The ninth has the leaves oblong and pointed, and frequently lyrate; they are jagged and acute-pointed, a little hoary on their underside, and stand on slender footstalks. The acorns are small, and have rough prickly cups. It is a native of the South of Europe.

There are several varieties.

The tenth species has several varieties, differing greatly in the size and shape of their leaves; but these will all arise from acorns of the same tree; even the lower and upper branches have very frequently leaves very different in size and shape, those on the lower branches being much broader, rounder, and their edges indented and set with prickles; but those on the upper long, narrow, and entire. The leaves are from three to four inches long, and an inch broad near the base, gradually lessening to a point; they are of a lucid green on their upper side, but whitish and downy on their under, stand upon pretty long footstalks, and do not fall till they are thrust off by young leaves in the spring. The acorns are smaller than those of the common oak, but of the same shape. It is a native of the South of Europe, Cochinchina, and Barbary.

The eleventh is hardly a distinct species from the common Evergreen Oak. It is a native of the South of France, and flowers in June.

The twelfth species has two or three varieties; one with a broad leaf, a second with a narrow leaf, both evergreen; and one or two which cast their leaves in autumn; but the broad-leaved evergreen is the most common. The leaves of this are entire, about two inches long, and an inch and quarter broad, with a little down on their under sides, on very short footstalks: these leaves continue green through the winter till the middle of May, when they generally fall off just before the new leaves come out; so that the trees are often almost bare for a short time. The acorns are very like those of the common oak. It is a native of the South of Europe, Barbary, &c.

The exterior bark forms the cork, which is taken from the tree every eight or ten years; but there is an interior bark which nourishes them, so that stripping off the outer bark is so far from

injuring the trees, that it is necessary to continue them; for, when the bark is not taken off, they seldom last longer than fifty or sixty years in health; whereas trees which are barked every eight or ten years will live 150 years or more. The bark of a young tree is porous and good for little: however, it is necessary to take it off when the trees are twelve or fifteen years old, for without this the bark will never be good: after eight or ten years, the bark will be fit to take off again; but this second peeling is of little use: at the third peeling the bark will be in perfection, and will continue so for 150 years, as the best cork is taken from old trees. The time for stripping the bark is in July, when the second sap flows plentifully: the operation is performed with an instrument like that which is used for disbarking the oak.

The thirteenth is of small growth, seldom rising above twelve or fourteen feet high, sending out branches the whole length on every side, so as to form a bushy shrub: the leaves are armed with prickles like those of the holly; the acorns are smaller than those of the common oak. The leaves resemble those of the *Ilex*, but are less, thinner, and green on both sides. It is a native of the South of Europe, the Levant, Barbary, &c., flowering in May.

From this species they collect the Kermes or scarlet grain, a little red gall, occasioned by the puncture of an insect called *Coccus ilicis*. With this the ancients used to dye cloth of a beautiful colour.

Culture.—These trees are all capable of being raised from the seed or acorns, which, in the common oak, should be gathered in autumn when quite ripe, just as they drop from the trees; but those of most of the foreign oaks are generally procured from abroad, and sold by the seedsmen.

All the sorts should be sown as soon after they are obtained as possible, as they are apt to sprout if they remain long out of the ground; and for their reception a spot of light ground in the nursery should be prepared by digging or ploughing, dividing it into four-feet-wide beds, in which the acorns should be sown, either in drills, two inches deep, in five or six rows, lengthwise of the bed: or rake the mould off the bed, the depth of two inches, into the alleys; then sowing the acorns all over the surface, about two or three inches apart, press them down with the spade, and spread the earth evenly over them two inches thick.

When they come up in the spring they should have occasional waterings and weeding; and when the plants are one or two years old, it is proper to plant them out in nursery-rows; this may be done in autumn, winter, or early in the

spring, taking them carefully up out of the seed-bed, shortening their perpendicular tap-roots, and trimming off any lateral shoots from the stem, leaving their top perfectly entire; then planting them in lines two feet and a half asunder, and fifteen or eighteen inches in the rows, where they should stand, with the usual nursery care, till of a proper size for final planting out either as forest-trees, or for ornament, training them up as full standards, with clean straight stems, and with their tops still entire.

But in raising the striped-leaved varieties of the common oak, and any particular variety of the other species, it should be by grafting, (as they will not continue the same from seed,) which should be performed upon any kind of oakling stocks raised from the acorns, and trained for standards as in the other kinds.

With respect to the final planting out, it may be performed in all the sorts of deciduous oaks any time in open settled weather, from November till February or March, and in the evergreen kinds in October, November, or the spring; and in a mild open season in any of the winter months.

When the trees of all the sorts are from about three or four to six feet stature, they are proper for being planted out for good, though, as forest- or timber-trees, it is better to plant them out finally while they are quite young, as from two to three or four feet in height; or when planted immediately from the seed-bed, where they are to remain, it may be advantageous, as the very young oaks root more freely than older trees, and take a freer growth. Those designed as forest- or timber-trees, should be planted in large open tracts of ground to form woods, placing them in rows only four or five to ten feet asunder, and from two or three to five or six feet in the rows, to allow for a gradual thinning. See PLANTATION and PLANTING.

Sometimes large plantations of these trees, for woods, are raised by sowing the acorns at once in the places where they are to remain; it being generally found that the trees raised at once from the acorn, from their not being checked, much outstrip the transplanted trees in their growth. The method of performing it is this: the ground being prepared by good ploughing and harrowing, in the autumn, having procured a proper quantity of acorns, draw drills across the ground four feet asunder, and two inches deep, dropping the acorns into them six or eight inches asunder, allowing for falling and thinning, covering them in evenly with the earth the depth of the drills; or instead of drilling them in, they may be planted with a dibble, the same depth and distance.

The general management of these trees in woods or timber plantations is the same as

Q U I

directed for forest-trees in general. See **PLANTATION**.

All the above sorts of trees may be employed to diversify large ornamental plantations in out-grounds, and in forming clumps in spacious lawns, parks, and other extensive open spaces: the evergreen kinds in particular have great merit for all ornamental purposes in pleasure-grounds and plantations. And all the larger growing kinds, both deciduous and evergreens, are highly valuable as forest-trees for timber; but the first sort claims precedence as a timber-tree, for its prodigious height and bulk, and superior worth of the wood.

In planting any of the species for ornament or variety in large pleasure-grounds, some may be disposed in assemblage in any continued plantation, some in clumps, and others singly.

QUICK, a term applied to signify any sort of young plant, but especially those of the white-thorn kind. By it is also often understood a live hedge, of whatever plants composed, in contradistinction to a dead hedge, but more properly the shrubs of which such live hedge is formed. In a strict sense it is however applied to the *Crataegus oxyacantha*, or Hawthorn, the young plants or sets of which are commonly sold by the nursery-gardeners under the name of Quick.

In the choice of these sets, those which are raised in the nursery are in general to be preferred to such as are drawn out of the woods, as the latter have seldom good roots: many persons, however, prefer them, as they are larger

Q U I

plants than are commonly to be had in the nursery. See **CRATÆGUS**.

QUINCUNX, in gardening, is a form of planting in which the trees are planted by fives, four of them forming a square, and the fifth placed in the middle,

thus * * and may be repeated over and

over in one continued plantation, with as many trees in several ranges as may be proper. It was formerly a fashionable mode of planting groves and other regular plantations. It is seen more fully below:

```

* * * * *
  * * * *
* * * * *
  * * * *
* * * * *
  
```

Something of this mode of arrangement has always a good effect in the disposition of shrubbery-plants, &c., though not in the regular order of it, but something nearly so, which gives the shrubs a greater scope of growth, and shows them to greater advantage. It is likewise a mode of planting that is proper in the kitchen-garden, in transplanting many kinds of esculent plants; such as lettuces, endive, strawberries, and even all the cabbage kinds, and many other plants, which gives them a greater scope to grow than if planted exactly square at the same distance from each other.

QUICKEN TREE. See **SORBUS**.

QUINCE TREE. See **PYRUS CYDONIA**.

R A C

RACER, a name applied to a sort of sward-cutter, or cutting implement used in racing out or cutting through the surface of grass sward, and dividing it into proper widths, lengths, and thickness, for turf intended to be cut up for laying in pleasure-grounds, and always necessary preparatory to the work of flaying or cutting up the turf with the turving-iron. It is also useful for cutting and straightening the edges of grass verges in such grounds.

It is a simple tool, consisting of a strong wooden handle about four feet long, having the cutter fixed at the lower end in the form of a half moon with the edge downward, to cut into the sward; the handle should be about an inch

R A C

and half thick, growing gradually thicker towards the lower end. See **PLATE ON IMPLEMENTS**.

In using it is pushed forward so as to cut or race out the sward in an expeditious manner.

In cutting turfs with it, it is necessary first to mark out on the sward the width of the turf intended, which should generally be a foot wide and a yard long, and about an inch or inch and a half deep; then strain a line tight, first lengthways, striking the racer into the sward close to the line, running it along expeditiously so as to cut its way, and divide the sward to a proper depth, afterwards placing the line a foot further, and racing it out as before, and so on to as many

widths as may be wanted; and then with the line placed crossways, to race out the sward accordingly in yard lengths. The sward being thus raced out, the turf-cutter with the turfing-iron should proceed to cut them up, and flay them off. See TURF.

RADISH. See **RAPHANUS**.

RADISH, HORSE. See **COCHLEARIA**.

RAGGED ROBIN. See **LYCHNIS**.

RAGWORT. See **SENECIO**.

RAKE, GARDEN, a well known sort of tool for raking the ground, as well as for putting in seeds, &c. with. In order to suit every kind of gardening work with rakes, there should be three or four different sizes, from about six to eighteen inches long in the head, having handles from six to eight feet in length, and the heads toothed with iron teeth two or three inches long, being placed from one to two inches asunder, according to the respective sizes.

The first or largest rake should have the head about fifteen to eighteen inches long, the teeth three inches, and placed two inches asunder, which is proper for raking stubborn or rough dug ground, and for putting in large kinds of seeds, raking off large weeds after hoeing, and many other purposes in large gardens.

The next size should have the head twelve inches long, the teeth three inches, being placed one inch and half asunder, which is proper for all common raking in ordinary light ground, and for raking in most kinds of small seeds, as well as other purposes.

A third sort of small rake should have the head about nine inches long, the teeth two and a half, being placed one inch asunder; proper for fine-raking beds, borders, &c., and raking in some particular fine seeds; as well as between rows, &c., of certain plants occasionally, where larger rakes cannot be introduced.

The smallest sort should have the head six inches long, the teeth two and a half, and placed one inch asunder; being very useful for raking between small plants in beds and borders and other small parts, where the plants stand close, as well as several other purposes of that kind.

These sorts of rakes are constructed both with wooden heads and iron teeth, and with the heads wholly of iron in both; of which the teeth are generally flattened, the back edge rounded off and narrowing gradually to the point, the other straight, and placed on the heads edge-ways across, with the back edge outward, and with the points all inclining very moderately inward, in a regular manner: the wooden-headed rakes having each end of the head hooped with a thin flat iron ring, to secure it from splitting.

The first sort are generally lightest and cheap-

est, being proper for any kind of garden raking; but the latter, or iron-headed rakes, when made neat, and as light as possible, with the teeth well set, in a proper position, and firmly fastened, are equally proper, and in some cases preferable, such as in wetish or moist soils, as not being liable to clog so much as wooden rakes, and more durable. They are, however, more proper for middling and small rakes, than for large ones; as, in strong raking, the teeth are more liable to get loose, than in the wooden-headed rakes.

Both the sorts, in their different sizes, are sold at the principal ironmongers' shops, both with and without handles.

Rakes having the heads, teeth, and handles, wholly of wood, are sometimes used for particular purposes; such as raking in light kinds of kitchen-garden seeds in light ground, and taking off large hoed-up weeds in wide clear spaces, raking up swaths of mowed short grass before the sweepers, also fallen leaves of trees in autumn, and clippings of hedges, &c., as well as several other uses.

RAKING, a necessary operation in gardening, to break the surface of the soil small, and render it fine for the reception of particular sorts of small seeds and plants previous to sowing and planting, as well as to render it neat and even.

It is also employed in raking in seeds, as being an expeditious mode of covering them in. In all kinds of small seeds of hardy plants, the ground being dug, &c., and the surface remaining rough after the spade, the seed is sown, and then raked in with an even hand, once or twice in a place, as a back and a fore stroke.

This operation is useful also among growing plants that stand distant enough to admit the rake, particularly where the surface is inclinable to bind; or where numerous small seed-weeds appear, as it loosens the soil, and retards the growth of the weeds, and promotes the growth of the young plants: it is also good culture at particular seasons, to annoy slugs, especially in kitchen gardens, to rake between the rows of small plants in autumn and winter, &c.

And raking the beds, borders, and other compartments of pleasure-grounds, now and then, smooth and even, gives an air of culture and neatness.

This sort of work should generally be performed in dry weather and when the ground is also moderately dry, as when done in rainy weather, or when the ground is very moist and cloggy, the surface is apt to cake and bind hard; this should be well attended to in sowing seeds. Rough dug ground does not rake well when it is

become very dry at top, especially if it was dug wet, and suffered to lie till the clods have become very dry and hard, in which case it will not rake well until mellowed or pulverised by a shower of rain. But common light garden ground generally rakes best when fresh dug, perhaps the same day, or day after at the furthest, before dried too much by the sun and wind, or rendered wet by rain, &c. The operation should, however, be performed when the ground is in such order as the clods will readily break and fall to pieces under the rake without clogging much thereto.

RAMPIONS. See **CAMPANULA**.

RAMSONS. See **ALLIUM**.

RANDIA. See **GARDENIA**.

RANUNCULUS, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Polyandria Polyginia*, and ranks in the natural order of *Multisiliquæ*.

The characters are: that the calyx is a five-leaved perianth: leaflets ovate, concave, coloured a little, deciduous: the corolla has five petals, blunt, shining, with small claws: the nectary a little cavity just above the claw, in each petal: the stamina have very many filaments, shorter by half than the corolla: anthers upright, oblong, blunt, twin: the pistillum has numerous germs, collected into a head: styles none: stigmas reflex, very small: there is no pericarpium: the receptacle connecting the seeds by very minute peduncles: the seeds very many, irregular, varying in figure, naked, with a reflex point.

The species cultivated are: 1. *R. Asiaticus*, Persian Crowfoot, or Garden Ranunculus; 2. *R. aconitifolius*, Aconite-leaved Crowfoot; 3. *R. acris*, Upright Meadow Crowfoot; 4. *R. repens*, Creeping Crowfoot; 5. *R. amplexicaulis*, Embracing-leaved Crowfoot.

There are other species that may be cultivated for variety.

The first has an upright branched stem, pubescent, round, as are also the peduncles: the lower leaves simple, lobed, gashed, acute, pubescent underneath, as are also the petioles: the root is composed of many thick fleshy fangs or fibres, uniting at top into a head; from these are sent forth many slender long fibres, striking deep in the ground: from the top arise several leaves, composed of three, six, or nine lobes of irregular forms, and cut at top into various segments; between these arise the flower-stalks, about a foot high, taper, hairy, and branching out at a little distance from the root: stem-leaves dividing into three parts, these again cut, and generally terminated by trifid points: the petioles are embracing at the base: the leaves

VOL. II.

are all hairy; the lower ones much larger and more compound than the upper: the flowers are terminating, with the stem naked for a considerable length below them. They vary much in size and colour, and the petals are frequently of different colours on the two surfaces. They appear in May; and in moderate seasons; or where they are shaded from the sun in the heat of the day, there will be a succession at least during a month: the seeds ripen in July. It is a native of the Levant.

The varieties are exceedingly numerous, being sometimes divided into two classes, as the Old Turkey kinds and the Persian kinds, the varieties of the latter amounting to many hundreds, and being considerably more various, rich, and beautiful in colour, than the others.

In the former of these they rise with a strong generally unbranching stalk a foot high, terminated by one large double flower, sometimes emitting one or two smaller ones from its sides, and of which there are red-flowered, scarlet-flowered, yellow-flowered, and scarlet turban-flowered, &c., being seldom tinged with different colours, as in the Persian kinds.

The latter rise eight or nine inches high, generally branching from the bottom, producing from five or ten to twenty or more flowers on each root, and of which there are single-flowered, semi-double-flowered, full-double-flowered, large and full like a double rose, being generally filled with petals to the very centre, forming a regular globular body, of admirable elegance, of all sorts of the most beautiful colours in different varieties, and of numerous degrees of deeper and lighter shades, stripes, and tinges in the several colours.

Martyn observes, that "the varieties produced of late years from the seeds of semi-double flowers are unbounded; and that Mr. Maddock remarks that they are more numerous than of any other flower. Accordingly his catalogue, he says, boasts nearly eight hundred, all with their proper names; ranged under the heads of—Dark and Dark Purple; Light Purple and Gray, &c.; Crimson, &c.; Reds, &c.; Rosy, &c.; Orange, &c.; Yellow and Yellow-Spotted, &c.; White and White-Spotted, &c.; Olive, &c.; Purple and Coffee-Striped, &c.; Red and Yellow-Striped; Red and White-Striped."

According to Mr. Maddock, "a fine Ranunculus should have a strong straight stem, from eight to twelve inches high. The flower should be of a hemispherical form, at least two inches in diameter, consisting of numerous petals gradually diminishing in size to the centre, lying over each other, so as neither to be too close nor too much separated, but having more of a per-

pendicular than horizontal direction, in order to display the colours with better effect. The petals should be broad, with entire well-rounded edges; their colours dark, clear, rich or brilliant, either of one colour or variously diversified, on an ash, white, sulphur or fire-coloured ground, or else regularly striped, spotted or mottled, in an elegant manner."

The second species is very handsome, three or four feet high and branched: the stem hollow within: the leaves large, digitate, three-lobed, divided to the base: segments lanceolate, serrate all round, somewhat hirsute, especially at the base: the flower white, terminating each branch. It is a native of the Alps of Europe.

There is a variety with double flowers, which has been obtained by seeds, and is preserved in many curious gardens for the beauty of its flowers. It is by some gardeners called *Fair Maid of France*. The root is perennial, and composed of many strong fibres: the leaves are divided into five lanceolate lobes: the four side-lobes are upon footstalks coming from the side of the principal stalk, and the middle one terminates it; they are deeply serrate, and have several longitudinal veins. The stalks rise a foot and a half high, and branch out at the top into three or four divisions, at each of which there is one leaf, of the same shape with the lower, but smaller. The flowers are pure white, and very double, each standing upon a short footstalk. It flowers in May.

The third has a perennial, tuberous root, with many long simple white fibres: the stem upright, about two feet high, round, hollow, having close-pressed hairs on it, not very leafy, much branched at top: the leaves are three-parted and five-parted, many-cleft; the segments black or deep purple at the points: the root-leaves on long upright petioles: the stem-leaves nearly sessile, less, and more finely cut: the uppermost linear and sessile: sheaths of the footstalks hairy. It flowers in June and July.

There is a variety with double flowers, which is the sort cultivated in the garden. It is frequent among other herbaceous perennials, under the name of *Yellow Bachelor's Buttons*.

The fourth species has a perennial root, consisting of numerous whitish fibres: the stems generally several from one root, a foot or more in length, beset with rough hairs, throwing out long creeping runners: the leaves are ternate, trifid and gashed, generally hairy on both sides, but sometimes smooth and shining, frequently marked with white (black) spots, on long hairy petioles dilated at the base: the leaflets also are on petioles, and are sometimes divided only into two segments: the leaves are broad, dark, and

distinctly divided twice: the uppermost are quite entire: the flowering-stems are erect, branched and leafy, generally supporting two flowers. It flowers in June.

There is a variety with double flowers, which is the sort cultivated in the gardens.

In the fifth the leaves in part surround the stalk at their base, whence the trivial name: in colour they differ from most others of the genus, being of a gray or more glaucous hue; which, joined to the delicate whiteness of the flowers, renders it very desirable in a collection of hardy herbaceous plants, more especially as it occupies little space, and has no tendency to injure the growth of others. It is a native of the Apennine and Pyrenean mountains, flowering in April and May.

Culture.—The first sort and the different varieties may be readily increased by the off-sets taken from the root, and new varieties may be raised from the seed.

In the first method the off-sets should be separated from the roots in dry weather, in the latter end of summer, when the flowering is over, and the stems and leaves are declining, being placed in bags or boxes, in a dry place, till the autumn, when they should be planted out in rows six or eight inches apart, and six of them in separate beds, prepared with light sandy earthy compost, to the depth of two or three feet, taking care to protect them carefully from the frost during the winter. When the buds begin to break through the ground they should be kept perfectly clear from weeds, protecting them from frosts; and when they have flowered and the stems are decayed, the root should be taken up, cleared from dirt, and placed in bags or boxes till the autumn, when they must be planted again.

In the second mode, the seed should be collected from the best plants, of the semi-double kinds, and be sown in flat pans or boxes, filled with light rich earth, in August, covering it in about a quarter of an inch thick with the same sort of earth, placing them in a shady situation, so as to have a little of the morning sun. The pots should remain here till the beginning of October, when the plants sometimes appear, though it is often later before this happens, when they should have a more open exposure with the full sun; but when frost is apprehended, they should be removed under a common hot-bed frame, being only covered in the nights and bad weather with the glasses, guarding them well against rains and frost.

In the spring following they should be exposed to the open air, being very slightly refreshed with water, having a situation to enjoy the

morning sun; and when their leaves and stems begin to decay, the roots may be taken up, dried in a proper place, and then put up in bags to be planted out in the same manner as the old roots in October.

In the following summer they will produce flowers; when such as are good should be marked, and the others removed from them. The plants intended to flower should not be suffered to run to seed, as roots which have produced seeds seldom furnish fine flowers afterwards. The disappointments experienced in purchasing these roots chiefly depend upon this circumstance.

The roots intended for the borders should be planted towards the spring in little clumps or patches, three, four, or five roots in each, putting them in either with a dibble or trowel about two inches deep and three or four asunder in each patch, and the patches from about three to five or ten feet distance, placing them in a varied manner in the borders.

In regard to their general culture after planting, such of the forward autumnal-planted roots of the choice sorts in beds as have shot above ground, should in winter, where convenient, have occasional shelter from hard frosts by mats supported on low hoop arches; or in very severe weather be covered close with dry long litter, removing all covering in open weather: and in the spring, when the flower buds begin first to advance, shelter them in frosty nights with supported mats, suffering them however to be open to the full air every day; but the latter plantings, that do not come up in winter or very early in spring whilst frosty nights prevail, will not require any protection, and all those distributed in patches about the borders must also take their chance in all weathers: those of the different seasons of planting will succeed one another in flowering from the beginning of April until the middle of June, though the May blow generally shows to the greatest perfection.

After the blow is past, and the leaves and stalks withered, the roots should be taken up and dried in the shade, then cleared from all offsets and adhering mould, putting them up in bags or boxes till next planting seasons, when they must be planted again as directed above.

In each season of planting, it is highly necessary, in the principal fine varieties, to put them either in entire new beds, or the old ones refreshed with some fresh rich earth or compost, working the old and new well together, in order to invigorate the growth of the plants.

The other species are capable of being easily raised by the roots, which should be slipped or parted in autumn when past flowering, or in the spring before they begin to shoot, and the slips

be either planted at once where they are to remain, or in nursery-rows for a season, then planted out finally. They succeed in any common soil and situation, and may be dispersed about the different flower-borders and clumps, where they constantly remain, only trimming them occasionally; and once in a year or two, or when they have increased into large bunches, taking them up in autumn or spring to divide them for further increase, replanting them again directly.

In saving seed for raising new varieties, it must be suffered to continue on the plant till it becomes brown and dry, then be cut off, and spread upon paper, in a dry room, exposed to the sun, and when quite dry be put into a bag, and hung in a dry place till it is wanted.

All these plants are highly ornamental; the first sort in beds and pots, and the other in the borders, clumps, and other parts of pleasure-grounds.

RAPE. See BRASSICA.

RAPHANUS, a genus containing plants of the herbaceous annual esculent kind.

It belongs to the class and order *Tetradynamia Siliquosa*, and ranks in the natural order of *Siliquosæ*.

The characters are: that the calyx is a four-leaved perianth, erect: leaflets oblong, parallel, converging, deciduous, gibbous at the base: the corolla four-petalled, cruciform: petals obcordate, spreading: claws a little longer than the calyx: nectariferous glands four; one on each side, one between the short stamen and pistil, and one on each side between the longer stamens and the calyx: the stamens have six, awl-shaped filaments, erect; of these, two that are opposite are of the same length with the calyx, and the remaining four are the length of the claws of the corolla: anthers simple: the pistillum is an oblong germ, ventricose, attenuated, the length of the stamens: style scarcely any: stigma capitate, entire: the pericarpium is an oblong silique, with a point, ventricose with little swellings, subarticulate, cylindrical: seeds roundish, smooth.

The species cultivated is: *R. sativus*, Common Garden Radish.

It has an annual root, large, fleshy, fusiform or subglobular, white within, red or white or black on the outside: the stem upright, thick, very much branched and diffused, rough with pellucid bristles: the leaves rough, lyrate: the calyx green, rough-haired: the petals pale violet, with large veins running over them: the pod long, with a sharp beak, fungous, white, with distant streaks, many-celled: cells membranaceous, closed, in a double longitudinal

row, along the middle septum: the seeds, one in each cell, but in each row from three to twelve, subglobular, large, ferruginous, covered with very minute raised dots. It is a native of China.

There are several varieties; some of which have the appearance of distinct species, from their shape, size, and colour of the roots; as the *Long-rooted*, which is that commonly cultivated in kitchen-gardens for its roots. Of this there are several subordinate variations: as the *Small-topped*, the *Deep Red*, the *Pale Red* or *Salmon*, and the *Long-topped Striped Radish*. The *small-topped* is most commonly preferred by the gardeners near London, as they require much less room than those with large tops; for as forward radishes are what produce the greatest profit to the gardener, and these are commonly sown upon borders near hedges, walls or pales, the large-topped sorts would be apt to grow mostly at top, and not swell so much in the root as the other, especially if the plants should be left pretty close.

The *Small Round-rooted*, which is not very common here, but in many parts of Italy it is the only one cultivated;—the roots of this are very white, round, small, and very sweet. It is now frequently brought to the London markets in the spring, generally in bunches, and is sometimes mistaken there for young turnips: when eaten young, it is crisp, mild, and pleasant.

The *Large Turnep-rooted* or *White Spanish*, which has a moderately large, spheroidal white root, and is esteemed chiefly for eating in autumn and the early part of winter. Both these sorts are commonly called indiscriminately Turnep Radishes.

The *Black Turnep-rooted Spanish*, which has a root like the preceding, white within, but with a black skin; and is greatly esteemed by many for autumn and winter eating.

Culture.—These are raised from seed by different sowings from the end of October till April or the following month. They should have a light fine mould, and the more early sowings be made on borders, under warm walls, or other similar places, and in frames covered by glasses.

The common spindle-rooted, short-topped sorts are mostly made use of in these early sowings, the seed being sown broadcast over the beds after they have been prepared by digging over and raking the surface even, being covered in with a slight raking. Some sow carrots with the early crops of radishes.

It is usual to protect the early sown crops in the borders, during frosty nights and bad weather, by mats or dry wheat straw, which should

be carefully removed every mild day. By this means they are brought more forward, as well as form better roots.

Where mats are used, and supported by pegs or hoops, they are readily applied and removed.

A second more general sowing should be made in January or February.

When the crops have got their rough leaf, they should be thinned out where they are too thick, to the distances of two inches, as there will be constantly more thinning by the daily drawing of the young radishes.

When the weather is dry in March, or the following month, the crops should be occasionally well watered, which not only forwards the growth of the crops, but increases the size of the roots, and renders them more mild and crisp in eating.

The sowings should be continued at the distance of a fortnight, till the latter end of March, when they should be performed every ten days, until the end of April or beginning of the following month. In sowing these later crops, it is the practice of some gardeners to sow coss-lettuces and spinach with them, in order to have the two crops coming forward at the same time, but the practice is not to be much recommended, where there is sufficient room.

In sowing the main general crops in the open quarters, the market-gardeners generally put them in on the same ground where they plant out their main crops of cauliflowers and cabbages, mixing spinach with the radish seed as above, sowing the seeds first, and raking them in, then planting the cauliflowers or cabbages; the radishes and spinach come in for use before the other plants begin to spread much, and as soon as those small crops are all cleared off for use, hoe the ground all over to kill weeds and loosen the soil, drawing earth about the stems of the cauliflowers and cabbages.

The Turnep Radish should not be sown till the beginning of March, the plants being allowed a greater distance than for the common spindle-rooted sort. The seeds of this sort are apt to degenerate, unless they are set at a distance from that kind.

The White and Black Spanish Radishes are usually sown about the middle of July, or a little earlier, and are fit for the table by the end of August, or the beginning of September, continuing good till frost spoils them. These should be thinned to a greater distance than the common sort, as their roots grow as large as turnips, and should not be left nearer than six inches.

To have these roots in winter, they should be drawn before hard frost comes on, and laid

in dry sand, as practised for carrots, carefully guarding them from wet and frost; as in this way they may be kept till the spring.

In regard to the culture of the general crops, they require very little, except occasional thinning where they are too thick, when the plants are come into the rough leaf, either by hoeing or drawing them out by hand; though for large quantities, small-hoeing is the most expeditious mode of thinning, as well as most beneficial to the crop by loosening the ground; in either method thinning the plants to about two or three inches distance, clearing out the weakest, and leaving the strongest to form the crop.

In order to save the seed, about the beginning of May some ground should be prepared by digging and levelling; then drawing some of the straightest and best-coloured radishes, and plant them in rows three feet distant, and two feet asunder in the rows; observing, if the season be dry, to water them until they have taken root: after which they will only require to have the weeds hoed down between them, until they are advanced so high as to overspread the ground.

When the seed begins to ripen, it should be carefully guarded against the birds. When it is ripe, the pods will change brown: then it must be cut, and spread in the sun to dry; after which it must be thrashed, and laid up for use where no mice can come at it.

Culture on Hot beds.—This method is sometimes practised in order to have the roots early, as in January or the following month. They should have eighteen inches depth of dung to bring them up, and six or seven inches depth of light rich mould. The seed should be sown moderately thick, covering it in half an inch thick, and putting on the lights: the plants usually come up in a week or less; and when they appear, the lights should be lifted or taken off occasionally, according to the weather; and in a fortnight thin the plants to the distance of an inch and half or two inches, when in six weeks they will be fit to draw. Where there are no frames to spare, the beds may be covered with mats over hoops, and the sides secured by boards and straw-bands. And when in want of dung, if the beds be covered with frames, and the lights put on at night and in bad weather, the plants may be raised for use a fortnight sooner than in the open borders.

RASPBERRY. See RUBUS.

RATTAN. See CALAMUS.

RATTLE, RED. See PEDICULARIS.

RATTLE, YELLOW. See RHINANTHUS.

RAUWOLFIA, a genus containing plants of the tender exotic shrubby kind for the stove.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Contortas*.

The characters are: that the calyx is a five-toothed perianth, very small, permanent: the corolla one-petalled, funnel-form: tube cylindrical, globular at the base: border five-parted, flat: segments roundish, emarginate: the stamina have five filaments, shorter than the tube: anthers erect, simple, acute: the pistillum is a roundish germ: style very short: stigma capitate: the pericarpium a subglobular drupe, one-celled, with a groove on one side: the seed two nuts, convex at the base, attenuated at the top, compressed, two-celled.

The species are: 1. *R. nitida*, Shining Rauwolfia; 2. *R. canescens*, Hoary Rauwolfia.

The first is a small tree, shining all over very much, upright, full of a white glutinous milk, twelve feet high: the leaves at the joints of the twigs in fours, lanceolate, quite entire, sharp, petioled; the two nearest five inches in length, twice as long as the two others. Common peduncles racemed, terminating, half an inch long, two or three together: the flowers small, without scent, having white petals. The fruits are at first yellowish, but at length become very dark purple, are milky, and three times as large as a pea: globular, fleshy, twin, two-seeded: the nuts or stones, like those of grapes, of a bony substance. It is a native of South America, flowering here from June to September.

The second species is an upright shrub, the whole of it milky, from one to eight feet in height, with all the parts of a corresponding size, according to the soil and situation. The younger branches subtomentose: the leaves in fours, obovate, attenuated to the base, acute, wrinkled, tomentose underneath, quite entire, the two nearest longer than the other two. Petioles hirsute, round. Common peduncles branched, terminating in fours. (Cymes peduncled, several, and two at the forkings of the stem.) Flowers reddish, small, without scent. It is a native of the Caribbee Islands, &c.

Culture.—These may be increased by the seeds or berries, which should be sown in pots filled with light mould, in the autumn or spring, plunging them in a mild hot-bed. When the plants have attained some growth, they should be removed into separate pots, and have the management of other exotic stove plants.

They may likewise be raised by layers and cuttings, laid down or planted out in pots, plunged in the hot-bed in the spring and summer months, till they have stricken root, being afterwards managed as those from seed.

They afford much ornament and variety in

hot-house collections, both in their foliage and flowers.

REED HEDGE, that sort of hedge or fence which is formed from reeds. They are a sort of temporary internal fences made with these dried materials which may be had cheap, and be expeditiously formed into hedges by the assistance of posts and railing, being of great utility for occasional use in gardens, to inclose particular internal spaces of ground, so as to afford shelter to certain seedling plants, both in nurseries and large kitchen-gardens; and in some nurseries, to form places of shelter for many sorts of seedling trees and shrubs, &c. which being tender whilst young, require the shelter of a fence in winter to break off severe or cutting blasts two or three years, till they gradually gather strength and a greater degree of hardiness. They are also useful in training several sorts of wall-fruit-trees against, to form them for rows, or what are called Trained Trees; admitting of planting trees against each side of them, six, eight, or ten feet asunder. See **NURSEY**.

In large open kitchen-gardens they are occasionally made use of to inclose the melonary, or place for raising early melons and cucumbers in, and often as cross internal fences, under which to form warm borders for the purpose of raising various early crops of esculents.

The proper sort of reeds for these fences are the dried stems of the common marsh reed, which grows in great plenty by river sides, and in lakes, and marshy places, furnishing a crop of stems annually fit to cut in autumn, when they should be bound in bundles, and stacked up, or housed to remain for use.

These fences are sometimes erected in fixed ranges, and sometimes formed into moveable pannels. In the first mode, some stout posts should be placed six or eight feet asunder, and five or six high, and from post to post carry two or three ranges of flat thin railing, one range near the bottom, another near the top, and a third in the middle; against this railing, the reeds must be placed about two inches thick, having other railing fixed directly opposite, so that the reeds being all along between the double railing, the bottoms resting either upon a plate of wood, or let into the ground, but the former is preferable; and as soon as one pannel is formed, the railing should be nailed as close as possible, driving some long spike-nails through each double railing, or binding them with strong withy bands, or tar rope-yarn, but nailing is the best, in order to bring them as close as may be, to secure the reeds firmly in the proper position; the top should be cut even afterwards.

In the better method, a frame-work of railing

should be prepared as above, each pannel six or eight feet long, and the reeds fixed therein as before directed; then, where they are intended to be placed, posts must be ranged six or eight feet distant to support the different pannels. Or sometimes the pannels may be placed inclining against the wall or other fence, in time of severe weather, when the borders are narrow. These sorts of fences are now in much less use in gardening than formerly.

RESEDA, a genus containing a plant of the flowering sweet-scented kind. It belongs to the class and order *Dodecandria Trigynia*, and ranks in the natural order of *Miscellanea*.

The characters are: that the calyx is a one-leaved perianth, parted: parts narrow, acute, erect, permanent; two of which gape more, for the use of the melliferous petal. The corolla consists of some petals (3. 5. 6.), unequal, some of them always half-three-cleft; the uppermost gibbous at the base, melliferous, the length of the calyx.

Nectary a flat upright gland, produced from the receptacle, placed on the upper side between the stamens and the uppermost petal, converging with the base of the petals. The stamens have eleven or fifteen short filaments. Anthers erect, obtuse, the length of the corolla. The pistillum is a gibbous germ, ending in some very short styles. Stigmas simple. The pericarpium is a gibbous capsule, angular, acuminate by means of the styles, gaping between them, one-celled: the seeds very many, kidney-form, fastened to the angles of the capsule.

The species cultivated is: *R. odorata*, Sweet Reseda, or Mignonette.

It has the root composed of many strong fibres, which run deep in the ground. The stems are several, about a foot long, dividing into many small branches. The leaves are oblong, about two inches in length, and three quarters of an inch broad in the middle, of a deep green colour. The flowers are produced in loose spikes at the ends of the branches, on pretty long stalks, and have large calices; the corollas are of an herbaceous white colour, and a fine smell. It is supposed a native of Egypt, flowering from June to winter. It is biennial.

Mr. Curtis observes, that "the luxury of the pleasure-garden is greatly heightened by the delightful odour which this plant diffuses; and as it grows more readily in pots, its fragrance may be conveyed into the house: its perfume, though not so refreshing perhaps as that of the sweet-briar, is not apt to offend the most delicate olfactories."

Culture.—This is raised from seed, which should be sown on a moderate hot-bed in March,

and when the plants are strong enough to transplant, be pricked out upon another moderate hot-bed to bring them forward, having a large share of air in warm weather to prevent their drawing up weak. Or they may be sown in pots of light mould and plunged in the hot-bed, which is probably the better practice. In the first mode, about the end of May the plants may be planted out, some into pots, to place in or near the apartments, and others into warm borders, where they may remain to flower and seed. The plants which grow in the full ground often produce more seeds than those which are in pots; but at the time when the seed-vessels begin to swell, the plants are frequently apt to be infested with green caterpillars, which, if they are not destroyed, eat off all the seed-vessels.

When the seeds are sown on a bed of light earth in April, the plants come up very well; and when not transplanted, grow larger than those which are raised in the hot-bed; but they do not flower so early, and in cold seasons scarcely ripen their seeds. In a warm dry border, however, the seeds often come up spontaneously, and grow very luxuriantly: but to have the flowers early in spring, the seeds should be sown in pots in autumn, being kept in frames through the winter, or on a gentle hot-bed in spring. The plants may also be preserved through the winter in a green-house, where they continue flowering most part of the year, but the second year they are not so vigorous as in the first.

It is cultivated for the fine fragrant smell which it affords.

REST HARROW. See *ONONIS*.

RHAMNUS, a genus furnishing plants of the tree and shrub kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Dumosa*.

The characters are: that there is no calyx, unless the corolla be taken for it: the corolla is an imperforate petal, externally rude, internally coloured, funnel-form: tube turbinate-cylindrical: border spreading, divided, acute: scalelets five, very small, each at the base of each division of the border, converging: the stamens have as many filaments as there are segments of the corolla, awl-shaped, inserted into the petal under the scalelet. Anthers small: the pistillum is a roundish germ. Style filiform, the length of the stamens. Stigma blunt, divided into fewer segments than the corolla: the pericarpium is a roundish berry, naked, divided into fewer parts internally than the corolla: the seeds solitary, roundish, gibbous on one side, flattened on the other.

The species cultivated are: 1. *R. catharticus*,

Purging Buckthorn; 2. *R. colubrinus*, Pubescent Rhamnus, or Buckthorn—Redwood; 3. *R. frangula*, Alder Buckthorn, or Berry-bearing Alder; 4. *R. paliurus*, Common Christ's-thorn; 5. *R. alaternus*, Common Alaternus; 6. *R. jujuba*, Blunt-leaved Buckthorn; 7. *R. oenophia*, Pointed-leaved Buckthorn; 8. *R. zizyphus*, Shining-leaved Buckthorn, or Common Jujube; 9. *R. Spina Christi*, Syrian Christ's-thorn.

The first rises with a strong woody stem to the height of twelve or fourteen feet, sending out many irregular branches: the young shoots have a smooth grayish-brown bark; but the older branches a darker and rougher bark, and are armed with a few short thorns. The leaves are two inches and a half long, by one and a quarter broad, dark green above but pale or light green beneath, having a pretty strong midrib, and several nerves proceeding from it, which diverge towards the sides, but meet again near the point: they stand upon pretty long slender footstalks. The flowers come out in clusters from the side of the branches: those of the male have as many stamens as there are divisions in the petal; those of the female (or hermaphrodite), have a roundish germ, which afterwards becomes a pulpy berry of a roundish form, inclosing four hard seeds. It is a native of Europe, flowering from the end of April to June, and ripening its berries about the end of September.

It is found that the juice of the unripe berries has the colour of saffron, and is used for staining maps or paper, being sold under the name of French berries: the juice of the ripe berries mixed with alum, is the sap-green of the painters; but if the berries be gathered late in the autumn, the juice is purple. The bark affords a beautiful yellow dye.

The second species is an upright tree, with most of the branches spreading out horizontally. The twigs, petioles, peduncles, lower surface of the leaves, and outer surface of the calyx, are covered with a slight ferruginous nap. The leaves are oblong-ovate, acute, entire, the upper surface smooth and shining, alternate, for the most part distich. The racemes short, corymbed, axillary, seven-flowered or thereabouts. The flowers are without scent, all pointing upwards, with greenish scales. It is a native of several islands in the West Indies, where it flowers in January, June, and November, but here in June.

The third rises with a woody stem to the height of ten or twelve feet, sending out many irregular branches, covered with a dark bark. The leaves are ovate-lanceolate, about two inches long and an inch broad, having several

transverse nerves from the midrib to the sides. the flowers are produced in clusters at the end of the former year's shoots, and also upon the first and second joints of the same year's shoot, each upon a short separate pedicel; they are small, of an herbaceous colour, and are succeeded by small round berries, which turn red, but are black when ripe. The flowers appear in June, and the berries ripen in September.

It is a native of most parts of Europe, flowering early in May, and sometimes in April.

The berries gathered before they are ripe, dye wool green and yellow—when ripe, blue-gray, blue, and green. The bark dyes yellow, and with preparations of iron, black.

There are two varieties, the broad-leaved, which has larger and rougher leaves—it grows naturally on the Alps; and the dwarf or round-leaved, which is of humble growth, seldom rising above two feet high—it grows on the Pyrenees.

The fourth species is a tree which rises with a pliant shrubby stalk to the height of eight or ten feet, sending out many weak slender branches, garnished with oval leaves placed alternately, standing upon footstalks nearly one inch long; these have three longitudinal veins, and are of a pale green. The flowers come out at the wings of the stalk in clusters, almost the length of the young branches; they are of a greenish-yellow colour, and appear in June, and are succeeded by broad, roundish, buckler-shaped seed-vessels, which have borders like the brims of a hat, the footstalks being fastened to the middle; these have three cells, each containing one seed. It is a native of the South of Europe, &c.

The fifth is a shrub with alternate, shining evergreen leaves, ovate, ovate-lanceolate, or lanceolate, often glandular at the base, having remote serratures about the edge. The flowers small, numerous, axillary, in short blunt racemes. There is a very small bracte at the base of each pedicel. The flowers are male and female or imperfect hermaphrodites, on the same or different individuals.

It is a native of the South of Europe and of Barbary. The fresh branches or young shoots, with the leaves, will dye wool a fine yellow. It flowers in April.

There are varieties with variegated leaves, commonly called Bloated Phillyrea by the nurserymen: and with the leaves striped with white and with yellow, called Silver and Gold-striped Alaternus.

The latter has the leaves much longer and narrower, and the serratures on the edges much deeper: this shoots its branches more erect,

forms a handsomer bush, and is equally hardy.

It is observed, that the Phillyrea is sometimes, and according to some, there are also the large-growing, the small-growing, the broad-leaved, the narrow-jagged-leaved, the yellow-striped jagged-leaved, the white-striped jagged-leaved—All which are confounded with the Alaternus, by such as are not botanists; but they may easily be distinguished by the position of their leaves, which are alternate in this, but placed opposite by pairs in that.

It is observed, that the Alaternus was much more in request formerly than at present; having been planted against walls in court-yards to cover them, as also to form evergreen hedges in gardens, for which purpose it is very improper, as the branches shoot very vigorously, and being pliant are frequently displaced by the wind; in winter, when much snow falls in still weather, the weight of it often breaks the branches; these hedges must also be clipped three times in a season to keep them in order, which is both expensive and occasions a great litter in a garden.

The sixth species is a tree with round branches. The leaves are very finely serrate, three-nerved, at the base on one side narrower, retuse, and there more deeply crenate, petioled. The flowers very many, axillary, each on very short pedicels, five-cleft, five-stamened; style bifid. Close to the petioles is a very small recurved prickly; but sometimes this is wanting. But according to Miller, it rises with shrubby stalks ten or twelve feet high, sending out many slender branches, which have a yellowish bark, and are armed with single recurved thorns (prickles) at each joint. The leaves are round, heart-shaped, about two inches in length and breadth, and indented at the footstalk; they have three nerves, and are covered with a yellowish down on their under side. The flowers come out in clusters from the wings of the branches, are small, of a yellowish colour, and succeeded by oval fruit about the size of small olives, inclosing a stone of the same shape. It is a native of the East Indies.

The seventh is a tree which has the leaves half-cordate or so on the upper side, but half-lanceolate on the hinder side, three-nerved, with the nerves branching, tomentose underneath, glaucous, on the wider side scarce manifestly serrate, petioled. In the axils on the opposite side are very many small clustered flowers, but on the same side with the petiole behind, is a recurved prickly. It is a native of the island of Ceylon.

In the eighth, according to Thunberg, the stem

is shrubby and branched; the branches and branchlets filiform and smooth; the prickles scattered, solitary or in pairs, commonly erect; the leaves alternate, on very short petioles, scarcely cordate, ovate and ovate-oblong, blunt with a very fine point, sometimes (but seldom) retuse, serrate, smooth, pale underneath, three-nerved, an inch long; the flowers axillary, two, three, or more together, very short and unequally peduncled; styles two, very short, with capitate stigmas. It is a native of the South of Europe, China, and Japan.

The fruit is sold in the market at Canton during the autumn. In Italy and Spain it is served up at the table in desserts during the winter season, as a dry sweetmeat.

The common or cultivated Jujube, according to Miller, has a woody stalk, dividing into many crooked irregular branches, armed with strong straight thorns, set by pairs at each joint: the leaves are two inches long and one broad, slightly serrate, on short footstalks: the flowers are produced on the side of the branches, two or three from the same place, sessile, small and yellow: the fruit oval, the size of a middling plum, sweetish and clammy, including a hard oblong stone, pointed at both ends.

The wild Jujube has slender woody stalks, which send out many weak branches, covered with a grayish bark, and armed with spines in pairs, one longer and straight, the other short and recurved: the leaves small, oval, veined, half an inch in length and breadth, and sessile. It is found about Tunis in Africa.

The ninth species sends up several shrubby stalks, dividing into slender branches, armed with straight spines, (prickles) set by pairs at each joint: the leaves are small, ovate, veined, alternate, upon very short footstalks: the flowers are small, yellow, axillary: the fruit round, about the size of the sloe. It is a native of Ethiopia.

Culture.—The first, third, and fourth sorts may be increased by seeds, layers, and sometimes by cuttings: the seeds should be sown in autumn as soon as ripe, on a bed of light earth, and slightly raked in: the plants mostly appear in the following spring, and when they have had a year or two's growth they should be planted out in nursery-rows, to have two or three years more growth, when they may be finally set out.

The layers should be made from the young shoots and be laid down in the autumn, in the usual way, giving a little twist or nick at the time, in the bark at a joint. They mostly become well rooted in twelve months.

Cuttings of the first and third sorts may be

made from the young twigs, and be planted in rows in the autumn, in a bed of good earth, when most of them will succeed.

The evergreen or Alaternus kinds may be raised from seeds and by layers. The plain sorts succeed in both methods, but the variegated sorts only with certainty by layers.

The seeds should be put into the ground in the early autumn in the same manner as above, and the layers laid down in the autumn as in the other kinds.

The other species may be raised by sowing the stones of the fruit in pots in the spring, plunging them in a moderate hot-bed. When the plants have attained some growth they should be removed into separate pots and managed as other tender plants.

They also succeed by suckers from the roots and layers as in the above sorts.

The sixth and eighth sorts may be placed in the green-house, and the others in the stove.

These are all ornamental plants; the hardy sorts for the pleasure-ground, and the more tender sorts for the green-house and stove, among other potted plants.

RHEUM, a genus containing plants of the herbaceous perennial luxuriant kind.

It belongs to the class and order *Enneandria Trigynia*, and ranks in the natural order of *Horaceæ*.

The characters of which are: that there is no calyx; or, which otherwise appears as the corolla, monopetalous, narrow at the base, and impervious, divided above into six parts, alternately smaller: the stamina have nine capillary filaments inserted into the corolla, and terminated by oblong didymous antheræ: the pistillum is a short triquetrous germen: the styles three, scarcely visible, and three reflexed plumose stigmas: there is no pericarpium, but one large, triquetrous, acute seed to each flower, having a membranous border.

The species chiefly cultivated are: 1. *R. Rhaponticum*, Rhapontic or Common Rhubarb: 2. *R. palmatum*, Palmated-leaved, or True Chinese Rhubarb: 3. *R. Compactum*, Compact Thick-leaved Rhubarb: 4. *R. undulatum*, Waved-leaved Chinese Rhubarb: 5. *R. ribes*, Wasted-leaved Persian Rhubarb: 6. *R. Tataricum*, Tartarian or Heart-leaved Rhubarb.

The first has a large, thick, fleshy, branching, deeply-striking root, yellowish within, crowned by very large, roundish-heart-shaped smooth leaves, on thick, slightly-furrowed footstalks; and an unusual upright strong stem, two or three feet high, adorned with leaves singly, and terminated by thick close spikes of white flowers. It is a native of Thrace and Scythia. This sort

is of inferior quality to some of the following; but the plant being astringent, its young stalks and footstalks of the leaves being cut and peeled in spring, are used for tarts and other culinary uses.

It is stated, on the authority of several cultivators of this plant, by the editor of Miller's Dictionary, that, by proper attention in the growth and preparation of the root, it may be obtained here nearly in equal goodness to the foreign.

The second species has a thick fleshy root, which is yellow within, crowned with very large palmated leaves, being deeply divided into acuminate segments, expanded like an open hand; the stems upright, five or six feet high or more, terminated by large spikes of flowers. This is said to be the true rhubarb.

The third has a large, fleshy, branched root, which is yellow within, and crowned by very large heart-shaped, somewhat lobated, sharply indented, thick smooth leaves; and an upright large stem, five or six feet high, garnished with leaves singly, and branching above; having all the branches terminated by nodding panicles of white flowers. It has been supposed to be the true rhubarb, which, however, though of superior quality to some sorts, is accounted inferior to the second sort.

The fourth species also has a thick, branchy, deep-striking root, which is yellow within, and crowned with large oblong, undulate, somewhat hairy leaves, having equal footstalks, and an upright firm stem, four feet high, garnished with leaves singly, and terminated by long loose spikes of white flowers.

The fifth has a thick fleshy root, and very broad leaves, full of granulated protuberances, and with equal footstalks; the stems upright, firm, three or four feet high, terminated by spikes of flowers, succeeded by berry-like seeds, being surrounded by a purple pulp. It is a plant of much singularity.

The sixth has a thick fleshy root, and heart-ovate, plane, smooth leaves; the petioles half cylindric-angled. It is a native of Tartary.

Culture.—These plants are all increased by seeds, which should be sown in autumn soon after they are ripe, where the plants are designed to remain, as their roots being large and fleshy when they are removed they do not recover it soon; nor do the roots of such removed plants ever grow so large and fair as those which remain where they were sown. When the plants appear in the spring, the ground should be well hoed over, to cut up the weeds; and where they are too close, some should be cut up, leaving them at the first hoeing six or eight inches asunder; but at the second, they may be separated to a foot and half distance or more. When

any weeds appear, the ground should be scuffled over with a Dutch hoe in dry weather; but after the plants cover the ground with their broad leaves, they keep down the weeds without any further trouble. The ground should be cleaned in autumn when the leaves decay, and in the spring, before the plants begin to put up their new leaves, be dug well between them. In the second year many of the strongest plants will produce flowers and seeds, and in the third year most of them. It is advised, that the seeds be carefully gathered when ripe, and not permitted to scatter, lest they grow and injure the old plants.

The roots continue many years without decaying; and it is said that the old roots of the true rhubarb are much preferable to the young ones.

These plants delight in a rich soil, which is not too dry nor over moist; and where there is a depth in such land for their roots to run down they attain a great size both in the leaves and roots.

Some cultivators think that the sowing is best performed in the later spring months; but in this way, as the seeds are slow in vegetating, there is much time lost. And a hot-bed has been sometimes employed, though it is not much advised.

The rhubarb plants may be also increased from offsets, separating some of the eyes or buds which shoot out on the upper parts of the root, together with a small part of the root itself, having some of the fibres to it. These offsets may be taken from roots of three or four years old, without any injury to the plant. By this method a year is saved, the plants are not in such danger of being devoured by vermin as those from seed, nor so uncertain in growing; they are not so tender, and only require keeping clear of weeds. There is no difference in the size of the roots thus raised, from those which grow from seeds. This method was practised by Mr. Hays, and in Mr. Hayward's practice several offsets were slipped from the heads of large plants in the spring, and set with a dibble about a foot apart. Four years after he took up the roots, and found them very large, and of excellent quality. "On further experience, when he took up his roots, either in spring or autumn, he divided the head into many parts; these he planted directly, at two feet distance, if intended for future removal; but if to remain for a crop, at four feet and a half."

In the culture of this root for medicinal uses the nature of the aspect is said not to be very material, provided it be not shaded too much on the south or west. The indispensable points are the depth and good quality of the soil, which should be light, loamy, and rich, but not too

much so, lest the roots be too fibrous: it can scarcely be too dry, for more evil is to be expected from a superabundance of moisture than from any actual want of it. If, with these advantages, the plantation can be placed on a gentle declivity, such a situation may be said to be the most desirable. Where a plantation does not possess the natural advantage of being on a declivity, narrower beds and deepened trenches are among the artificial means that should be adopted; but most situations will require some care to prevent the ill effects of water remaining on the crowns of the plants: therefore, when the seedstalks are cut off, which ought always to be done immediately upon the withering of the radical leaves, they should be covered with mould in form of a hillock. This process will answer two good purposes; that of throwing off the rain, and keeping open the trenches by taking the earth from them.

It is observed that, the injuries to which the young plants are most liable, are from slugs and other small vermin, from inattention to the season and manner of planting, and from too great an exposure to frost. Little damage is to be feared from heat; and in general they are hardy and easy of cultivation when arrived beyond a certain term.

It is advised to take great care of the nursery-bed, as the pains bestowed by constant waterings, and protecting the young plants from the ravages of insects, will amply repay the planter. Roots that thrive well here, will in three years arrive at an equal size with others, that have not succeeded so well, at the end of five. When a plantation is to be formed, or a vacancy filled up, select the finest and most thrifty plants. No plant will come to any thing when it has lost its principal bud.

It is observed, that there is a difference of opinion in respect to the age at which the roots ought to be taken up for use; but is probably best done from four to eight years.

It is best taken up in the autumn in a dry time, and should be immediately dried and prepared by cutting into pieces and cleaning.

Some plants of each of the sorts may also be introduced in the dry borders and clumps for the ornamental effect of the leaves and flowers.

RHEXIA, a genus containing plants of the hardy herbaceous perennial kind. It belongs to the class and order *Octandria Monogynia*, and ranks in the natural order of *Calycanthemæ*.

The characters are: that the calyx is a one-leaved perianth, tubular, ventricose at bottom, oblong, with a four-cleft border, permanent: the corolla has four roundish petals inserted into the calyx, spreading: the stamina have eight

filiform filaments longer than the calyx, and inserted into it: anthers declining, grooved, linear, blunt, versatile: the pistillum is a roundish germ: style simple, the length of the stamens declining: stigma thickish, oblong: the pericarpium is a roundish four-celled, four-valved, capsule, within the belly of the calyx: the seeds numerous, roundish.

The species are: 1. *R. virginica*, Virginian Rhexia: 2. *R. Mariana*, Maryland Rhexia.

The first rises with an erect stalk near a foot and half high, four-cornered and hairy: the leaves lanceolate, hairy, about two inches long, and half an inch broad, entire and opposite: the stalk has two peduncles coming out from the side opposite to each other at the upper joint, and is terminated by two others; these each sustain two or three red flowers with heart-shaped petals, spreading open in form of a cross, and appear in June. It is a native of North America.

The second species sends up an erect stalk about ten inches high: the leaves lanceolate, about an inch long, and a third part of an inch broad, set on by pairs; and from every joint of the stalk two short shoots come out opposite, with small leaves of the same shape; the whole plant is thick set with stinging iron-coloured hairs: the stalk divides at the top into two peduncles, spreading from each other, having one or two reddish flowers on each, with a single subsessile flower between them; they have four heart-shaped petals, which spread open as in the preceding. It flowers about the same time, and is a native of Maryland, Brasil, Surinam, &c.

Culture.—These plants may be increased by sowing the seeds procured from their native situations, in the autumn or spring, in pots filled with good fresh mould, placing them under the protection of frames, or if in a mild hot-bed they will be rendered more forward. When sown at the latter season, the plants seldom appear the same year. When the plants have attained sufficient growth they should be planted out partly in a dry sheltered east border and partly in pots, to have the protection of a frame against the frosts in winter. They flower the second year, and with care continue three or four.

They afford ornament in the borders as well as among flowery potted plants.

RHODIA. See **RHODIOLA**.

RHODIOLA, a genus comprising a plant of the low herbaceous, odoriferous, succulent perennial kind. It belongs to the class and order *Diœcia Octandria*, and ranks in the natural order of *Succulentæ*.

The characters of which are: that in the

male, the calyx is a four-parted perianth, concave, erect, obtuse, permanent: the corolla has four oblong obtuse petals, from erect-spreading, double the length of the calyx, deciduous. Nectaries four, erect, emarginate, shorter than the calyx: the stamens have eight awl-shaped filaments longer than the corolla. Anthers simple: the pistillum has four oblong acuminate germs. Styles and stigmas obsolete: the pericarpium is abortive: female: the calyx is a perianth as in the male: the corolla has four petals, rude, erect, obtuse, equal with the calyx, permanent. Nectaries as in the male: the pistillum is as four oblong acuminate germs, ending in simple straight styles: stigmas obtuse: the pericarpium has four horned capsules opening inwards: the seeds very many, roundish.

The species cultivated is: *R. rosea*, Common or Yellow Rosewort.

It has a very thick fleshy root, which when bruised or cut sends out an odour like roses; with many heads, whence in the spring come out thick succulent stalks about nine inches long, closely garnished with thick succulent leaves of a gray colour, an inch long, and half an inch broad, indented on their edges towards the top, and placed alternately on every side the stalk; which is terminated by a cluster of yellowish herbaceous flowers, male and female, on distinct plants appearing early in May. They have a very agreeable scent, but are not of long continuance. It is a native of Lapland.

There is a variety in which the roots are smaller; the stalks small, and not above five inches long; the leaves small, ending with a purple point; the petals are purplish, and the stamens little longer than the petals. It flowers later.

Culture.—This plant may be increased by planting cuttings of the stalks in the beginning of April, soon after they come out from the head, in a shady border; covering them close down with a glass, and keeping them dry, when they mostly put out roots in about six weeks; but the cuttings should be laid in a dry room at least a week before they are planted out, otherwise they are apt to rot, and be destroyed.

They may also be raised by parting the roots in the beginning of autumn, when the stalks begin to decay; and when the fleshy parts are cut or broken they should be laid to dry a few days before they are planted. They require a shady situation, and a dry undunged soil, in which they will continue many years. They afford variety in the borders, clumps, &c.

RHODODENDRUM, a genus containing plants of the hardy, deciduous, and evergreen, flowering, shrubby kinds, Dwarf Rose-bay.

It belongs to the class and order *Decandria*

Monogynia, and ranks in the natural order of *Bicornes*.

The characters are: that the calyx is a five-parted permanent perianth: the corolla one-petalled, wheel-funnel-form: border spreading, with rounded segments: the stamens have ten filiform filaments, almost the length of the corolla, declined. Anthers oval: the pistillum is a five-cornered retuse germ. Style filiform, the length of the corolla. Stigma obtuse: the pericarpium is an ovate capsule, subangular, five-celled, divisible into five parts: the seeds numerous, very small.

The species are: 1. *R. ferrugineum*, Rusty-leaved Rhododendron: 2. *R. hirsutum*, Hairy Rhododendron: 3. *R. chamæcistus*, Dwarf Rhododendron, or Rose-bay: 4. *R. ponticum*, Purple Rhododendron: 5. *R. maximum*, Broad-leaved Rhododendron.

The first rises with a shrubby stalk near three feet high, sending out many irregular branches, covered with a purplish bark. The leaves are lanceolate, an inch and half long, and half an inch broad in the middle, entire, with reflexed borders, lucid green on their upper surface, and rusty-coloured underneath, placed all round the branches without order. The flowers are produced in round bunches at the ends of the branches: the corolla is funnel-shaped with a short tube, and is cut into five obtuse segments at the brim, spreading a little open, and of a pale rose colour. It is a native of Switzerland, flowering from May to July.

The second species seldom rises two feet high, and sends out many short woody branches, covered with a light brown bark. The leaves are ovate-lanceolate, about half an inch long, and a quarter of an inch broad, sitting pretty close to the branches; they are entire, and have a great number of fine ferruginous hairs on their edges and under side. The flowers are produced in bunches at the ends of the branches. The tube of the corolla is about half an inch long: the five segments of the brim are obtuse, spread half open, and are of a pale red colour. It is a native of the mountains of Switzerland.

The third is a small shrub, very much branched, the extreme branches leafy. The leaves are oblong, hard, on short reddish petioles. The peduncles one, or more, an inch long, villose, reddish brown, terminating. Calyx deeply five-cleft, of the same colour with the peduncle; the segments acute. The corolla purple, the segments ovate. The stamens longer than these. The style longer than the stamens. It is a native of Austria, &c.

The fourth species has an upright trunk, shrubby, commonly the height of a man, but

Rhododendron ponticum
1 Pontic Rhododendron

Robina hispida
2 Rose acacia

sometimes only half so high, frequently thicker than the human arm, very much branched from the bottom irregularly; the wood white, the bark ash-coloured. The branches round, scarred, with a smoothish testaceous bark. The leaves alternately scattered, coriaceous, large, quite entire, very smooth, becoming ferruginous underneath, scarcely nerved except the midrib, having a longitudinal streak on the upper surface, of a wide-lanceolate form, more attenuated towards the thick petiole. The flowering-buds formed in autumn for the year following, and consisting of ferruginous, ovate-acute, concave, very smooth, imbricate scales. The flowers in a short raceme at the end of the branchlets, about ten, and very handsome. It is a native of the Levant, flowering in May and June.

The fifth rises in its native soil, fifteen or sixteen feet high, with a shrubby stalk, sending out a few branches towards the top. The leaves stiff, smooth, six inches long and two broad, of a lucid green on their upper side, and pale on their under, whilst young; but afterwards changing to the colour of rusty iron: they have short thick footstalks, and are placed without order round the branches: between these the buds are formed for the next year's flowers; these swell to a large size during the autumn and spring months till the beginning of June, when the flowers burst out from their covers, forming a roundish sessile bunch or corymb. It is a native of North America, flowering here from June to August.

Culture.—These plants may be increased by sowing the seeds, which are very small, as soon as possible after they are procured, either in a shady border, or in pots filled with fresh loam, having them very lightly covered with a little fine mould, and plunging the pots up to their rims in a shady border, and in hard frost covering them with bell- or hand-glasses; taking them off in mild weather. When they are sown early in autumn, the plants come up the following spring, when they must be kept shaded from the sun, especially the first summer, and duly refreshed with water; in the autumn following removing them to a shady situation, on a loamy soil, covering the ground about the roots with moss, to guard them from frost in winter and keep the ground moist in the summer season.

They may also be increased from suckers or offsets, which they produce plentifully where they grow naturally, but seldom in this climate.

They are very ornamental in the border, clumps, and other parts of shrubberies.

RHUBARB. See **RHEUM.**

RHUS, a genus containing plants of the tree and shrub kinds; Sumach and Toxicodendron.

It belongs to the class and order *Pentandria Trigynia*, and ranks in the natural order of *Dumosæ*.

The characters are: that the calyx is a five-parted perianth, inferior, erect, permanent: the corolla has five ovate petals, from upright spreading; the stamina have five very short filaments: anthers small, shorter than the corolla: the pistillum is a superior roundish germ, the size of the corolla: styles scarcely any: stigmas three, cordate, small: the pericarpium is a roundish one-celled berry: the seed one, roundish, bony.

The species are; 1. *R. coriaria*, Elm-leaved Sumach; 2. *R. typhinum*, Stag's Horn Virginian Sumach; 3. *R. glabrum*, Scarlet Sumach; 4. *R. elegans*, Carolina Sumach; 5. *R. copallinum*, Lentiscus-leaved Sumach; 6. *R. cotinus*, Venice Sumach; 7. *R. toxicodendron*, Trailing Poison-oak, or Sumach; 8. *R. vernix*, Varnish Sumach; 9. *R. radicans*, Rooting Poison-oak, or Sumach; 10. *R. tomentosum*, Woolly-leaved Sumach; 11. *R. angustifolium*, Narrow-leaved Sumach; 12. *R. lucidum*, Shining-leaved Sumach.

The first has a strong woody stem dividing into many irregular branches, and rises to the height of eight or ten feet; the bark is hairy, and of an herbaceous brown colour whilst young. The leaves are composed of seven or eight pairs of leaflets terminated by an odd one: these leaflets are about two inches long, and half an inch wide in the middle, and of a yellowish green colour. The flowers grow in loose panicles at the end of the branches, each panicle being composed of several thick spikes of flowers sitting close to the footstalks: they are of a whitish herbaceous colour, and appear in July. It grows naturally in Italy, Spain, &c.

The branches are used instead of oak-bark for tanning leather, and it is said that Turkey leather is all tanned with this shrub.

The second species has a woody stem, from which are sent out many irregular branches, generally crooked and deformed. The young branches are covered with a soft velvet-like down, greatly resembling that of a young stag's horn both in colour and texture, whence it has vulgarly the name of the Stag's Horn Tree. The leaves have six or seven pairs of leaflets, terminated by an odd one; their under surface and the midrib are hairy. The flowers are produced in close tufts at the end of the branches in July, and are followed by seeds, inclosed in purple woolly succulent covers, so that the bunches are of a beautiful purple colour in autumn: the

leaves also then change first to a purplish, and, before they fall, to a feuilletmort colour. It is a native of Virginia and Carolina.

The third is not so high as the second; the branches are much more spreading and smooth, the leaflets are wider and less serrate, they are of a deeper green, and have only a hoary cloud or bloom on the under surface, which may be wiped off with the fingers; whereas in that they are covered with a hoary pubescence; the panicle is more diffused. It is a native of North America.

There are several varieties; as the New England Sumach; in which the stem is stronger, and rises higher than that of the second sort; the branches spread more horizontally, they are not quite so downy, and the down is of a brownish colour; the leaves are composed of many more pairs of leaflets, and are smooth on both sides: the flowers are disposed in loose panicles, and are of an herbaceous colour. The Canada Smooth Red Sumach, which has smooth branches of a purple colour, covered with a gray pounce: the leaves are composed of seven or eight pairs of leaflets which are four inches and a half long, and one inch broad in the middle, terminating in acute points, and a little serrate, of a lucid green on their upper surface, but hoary on their under, and smooth: panicle large, composed of several smaller, each on separate footstalks, the whole covered with a gray pounce: the flowers are of a deep red colour.

The fourth species rises commonly to the height of seven or eight feet, and divides into many irregular branches, which are smooth, of a purple colour, and pounced over with a grayish powder; as are also the petioles, which are of a purplish colour. The leaves have seven or eight pairs of lobes, not always exactly opposite; they are three or four inches long, and almost an inch broad in the middle; above they are of a dark green, underneath hoary but smooth. The flowers of a bright red colour, in very close thick large panicles, appearing in July and August, and continuing till autumn. It is a native of South Carolina.

The fifth seldom rises more than four or five feet high, dividing into many spreading branches, which are smooth, of a light brown colour, and pretty closely furnished with pinnate leaves; these have four or five pairs of narrow leaflets, which are entire, two inches long and half an inch broad, ending in acute points; of a light green on both sides, and in autumn change to purple: the petiole has on each side a winged or leafy border, running from one pair of leaflets to another, ending in joints at each pair. The flowers are produced in loose panicles at the end

of the branches, of a yellowish herbaceous colour, and appear in July. It is a native of North America.

The sixth species rises with an irregular shrubby stalk to the height of ten or twelve feet, sending out many spreading branches covered with a smooth brown bark, garnished with single obovate leaves about two inches long, and of the same breadth, rounded at their points, and stand upon long footstalks; are smooth, stiff, and of a lucid green, having a strong midrib, whence several transverse veins run towards the border. The flowers come out at the end of the branches upon long hair-like footstalks, which divide and branch into large hair-like bunches of a purplish colour; are small, white, and composed of five small oval petals, which spread open. They appear in July. It is a native of the South of France, &c.

The root is used for dyeing: the leaves and young branches dye black; and the bark is used for tanning leather.

The seventh has the stalks rising higher than those of the ninth sort; the branches are slender but woody, and have a brown bark: the leaves are on pretty long petioles; leaflets oval, two inches long, one inch and a half broad, indented angularly, and hoary on their under side: the male flowers, which are produced on separate plants from the fruit, come out from the side of the stalks in close short spikes, and are of an herbaceous colour: the females are produced in loose panicles, agree in shape and colour with the males, but are larger and have a roundish germ supporting three very short styles. It is a native of many parts of North America.

The eighth species has a straight trunk: the leaflets four or five pairs, sometimes more, the upper surface green and smooth, the lower paler and pubescent, entire about the edge, or sometimes slightly sinuate, with oblique superficial veins, and the midrib inclining to the inner side, except in the odd leaflet, which it divides into equal parts: the petioles oblong, purple: from the base of these come out the peduncles, which are green, and bear many flowers in a racemed spike; these are small and herbaceous: fruit a juiceless drupe, slightly compressed. It is common in swamps in North America. Flowers here in July.

Martyn says, that "the milky juice stains linen a dark brown. The whole shrub is, in a high degree, poisonous; and the poison is communicated by touching or smelling any part of it."

The ninth has a low shrubby stalk, which seldom rises more than three feet high, sending out shoots near the bottom, which trail upon the ground, putting out roots from their joints,

whereby it multiplies and spreads greatly. If it be near a wall, the fibres will strike into the joints and support the stalks when severed from the root. When it is thus supported, the stalks become more woody, and rise much higher than when it trails on the ground. The petioles are near a foot long; the three leaflets are ovate-cordate, five inches long, three inches and a half broad, each on a short petiole; the two side ones oblique to the petiole, but the middle one equal; they have many transverse veins running from the midrib to the borders. The flowers come out from the side of the stalk in loose panicles, are small and of an herbaceous colour, male and female on distinct trees; the latter succeeded by roundish, channelled, smooth berries, of a gray colour, inclosing one or two seeds. It grows naturally in many parts of North America, and flowers in July.

Having, in common with ivy, the quality of not rising without the support of a wall, tree, or hedge, it is called in some parts of America Creeping Ivy. It will climb to the top of high trees in woods, the branches every where throwing out fibres that penetrate the trunk. When the stem is cut, it emits a pale brown sap of a disagreeable scent, and so sharp that letters or marks made upon linen with it cannot be got out again, but grow blacker the more it is washed.

Like *Rhus vernix* it is poisonous to some persons, but in a less degree. Kalm relates, that of two sisters, one could manage the tree without being affected by its venom, whilst the other felt its exhalations as soon as she came within a yard of it, or even when she stood to leeward of it at a greater distance; that it had not the least effect upon him, though he had made many experiments upon himself, and once the juice squirted into his eye; but that on another person's hand, which he had covered very thick with it, the skin, a few hours after, became as hard as a piece of tanned leather, and peeled off afterwards in scales.

There is a variety with a straight and stout trunk, having a brownish ash-coloured bark: the leaves smooth, veined, bright green above, somewhat paler underneath, pendulous, and somewhat bent back: in the male plant the leaves are rather wider and longer, and are drawn more to a point; in the female they are shorter and blunter, and the petioles are reddish, whereas in the other they are green: the flowers axillary, in racemes; the males larger, whitish yellow; the females smaller, herbaceous, on the germ instead of the style there are two, sometimes three black dots: fruits round, the size and form of coriander seeds, streaked with five lines, remaining on the tree till new flowers

come out; when the outer rind comes off, and a cretaceous substance comes into view, in which an ash-coloured, hard, horny seed is involved, slightly divided on the upper part, and somewhat kidney-shaped.

The tenth rises with a woody stalk to the height of seven or eight feet, covered with a brown bark, and having many irregular branches: the leaves on long petioles: the leaflets angular, near two inches long and one inch broad, dark green above, downy underneath: the flowers come out in slender bunches from the side of the branches, are of a whitish herbaceous colour, and soon fall away. It is a native of the Cape.

The eleventh species rises with a woody stalk seven or eight feet high, dividing into several irregular branches, covered with a dark brown bark: the leaves are on pretty long footstalks: the leaflets two inches long and half an inch broad in the middle, ending in acute points, lucid green above, but downy underneath: the flowers are produced in small loose bunches from the side of the branches; are small and herbaceous. It is a native of the Cape.

The twelfth rises with a woody stalk dividing into many branches, covered with a brown bark: the leaflets are of a lucid green colour. It is a native of the Cape, flowering in July and August.

Culture.—The first nine of these plants are capable of being raised by seeds and layers, and some of them also by suckers, or their rooting branches.

In the first method, such of them as do not send up suckers should have the seed procured from abroad, and sown in pots of a large size or in beds of light mould, being covered in about the depth of half an inch in the autumn. Those in pots should be protected from the frosts during the winter, and if plunged in a moderate hot-bed in the early spring they will be rendered more forward, letting the plants have a free air when they appear. Those in the open ground often remain long before they vegetate; they should be kept free from weeds, be well watered in summer, and have the protection of mats the first winter. When the plants have had the growth of a year or two they may be planted out in nursery-rows till fit to be set out in the places where they are to remain. The potted plants should have the protection of the frame the second winter, air being freely admitted in mild weather: and in the spring following they may be shaken out of the pots without injuring the roots, and be set out in nursery-rows, three feet apart, and a foot distant in the rows, where they may remain two years, and then be planted out where they are to remain.

Such sorts as have young branches sufficiently low, may have them laid down in the autumn in the slit method; when they will mostly have stricken root in the course of a year, and may be taken off and planted out where they are to remain, or in the nursery.

Those sorts that send up suckers from the roots should have them taken up during the winter, and planted out in nursery-rows in the manner of the seedlings, till of a proper growth to be planted out.

The seventh and ninth sorts may likewise be increased by their trailing branches, which have stricken root as they rest on the ground, which should be taken up with their roots entire in the autumn, winter, or any early spring, and be planted out either where they are to remain or in nursery-rows, till of sufficient growth for the purpose they are intended.

The first and fourth sorts being the most tender require the most sheltered situations.

Most of these plants afford a milky juice, which is extremely acrid and corrosive.

The three last sorts may be raised by cuttings and layers with great facility.

In the first method, the cuttings of the young shoots should be planted out in pots of light fresh mould, in the spring and early summer months, plunging them in a moderate hot-bed, where they readily strike root, being occasionally watered and shaded; and when they have formed good roots they may be potted off into separate pots.

In the latter mode any of the young wood may be laid down in the usual manner, in the early spring, when by the autumn they will mostly have stricken good root, and may be taken off, and be potted out the same way as the cuttings.

The first nine sorts have a fine effect in mixture with other deciduous shrubby plants, in the borders, clumps, and other parts of pleasure-grounds; and the three last afford variety among other potted green-house plants of the less tender kinds.

RHUS COBBE. See **SCHMIDELIA**.

RIBES, a genus containing plants of the hardy deciduous shrubby kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Pomaceæ*.

The characters are: that the calyx is a one-leaved perianth, half-five-cleft, ventricose: segments oblong, concave, coloured, reflex, permanent: the corolla has five, small, obtuse petals, erect, growing to the margin of the calyx: the stamina have five, subulate, erect filaments, inserted into the calyx: anthers incur-

bent, compressed, opening at the margin: the pistillum is a roundish germ, inferior: style bifid: stigmas obtuse: the pericarpium is a globose berry, umbilicated, one-celled: receptacles two, lateral, opposite, longitudinal: the seeds very many, roundish, somewhat compressed.

The species cultivated are: 1. *R. rubrum*, Common Currant; 2. *R. nigrum*, Common Black Currant; 3. *R. Grossularia*, Rough-fruited Gooseberry; 4. *R. Uva crispa*, Smooth-fruited Gooseberry; 5. *R. reclinatum*, Procumbent Gooseberry; 6. *R. oxyacanthoides*, Hawthorn-leaved Currant; 7. *R. cynosbati*, Prickly-fruited Currant.

The first has smooth branches: the leaves on longish petioles, doubly serrate, subpubescent: the racemes simple, nodding, when in fruit pendulous: the bracte ovate, small, shorter than the pedicels: the corolla yellowish green, with obcordate petals: the berries acid, shining. It is a native of Europe, flowering in May.

It is observed by Martyn, that this shrub is very apt to be infested with the *Aphis Ribes*, in which case the green leaves become red, pitted, and puckered. It has been long cultivated in the garden and greatly improved. There are several varieties: as the common sort with small red fruit; with white fruit, with pale fruit, commonly called the Champaign Currant, differing only in being of a pale red or flesh colour. But since the White and Red Dutch Currants have been introduced and become common, the old sorts have been almost banished, and are now rarely to be found.

Mr. Forsyth mentions the Fine new white Dutch, Long-branched red, Striped-leaved red white Currant, and Large pale and red Dutch.

There are also the Sweet Currant, the Small-fruited Currant, and a variety with blotched leaves, which is kept in some plantations; but as the variegation is apt to go off when the plant is vigorous, it scarcely deserves a place in them.

The second species is distinguished by its more humble habit, its strong-smelling leaves glandular underneath, its hairy racemes, tubular calyx, and black fruit, but especially by its solitary, one-flowered peduncle at the base of the raceme, and distinct from it: the buds are glandular: the bractes woolly, and as long as the pedicels: the flowers villose, turban-shaped; the petioles also subvillose and glandular. It is a native of most parts of Europe, flowering in May.

There is a sort often termed the American Black Currant. The berries have a very peculiar flavour, which many persons dislike; but are commonly eaten in puddings in some parts, and make a tart little inferior to the Cranberry.

The juice is frequently boiled down to an extract, with the addition of a small proportion of sugar; in this state it is called Rob, and used in sore throats.

Currants are by some supposed the most useful of all the small fruits, either for table or culinary uses, as well as for wine, continuing long in succession with due management. The black sort is seldom sent to table.

This sort may be infused in spirit of any kind, in which way they make a good liquor.

The third is a low branching shrub: the prickles under the buds one, two, or three: the leaves three-lobed, gashed, subpubescent: the petioles hairy, commonly longer than the leaves: the peduncles one-flowered, nodding, having one, two or three opposite ovate ciliate bractes in the middle: the germ villose: the berries pendulous, hairy.

It is observed by the editor of Miller's Dictionary, that if the bractes do not distinguish this from the following, the roughness or smoothness of the berries will hardly do it, as Mr. Robson has found that seeds from the same plant will produce both rough and smooth fruit. He cannot regard them as different species. It is a native of several parts of Europe.

The fourth sort has the buds woolly: the calyx bent back: the peduncle woolly: the bracte ovate, embracing, generally with three divisions: the flowers solitary, pendent: the stipule, ciliate with knobbed hairs: a triple thorn beneath the buds: the berry crowned with the permanent calyx, peduncled, pulpy, subdiaphanous, pale, amber-coloured, red or purple, smooth, the pulp watery and sweet: receptacles formed of the skin of the berry thickened, oblong, narrow; with filiform umbilical chords, the length of the seeds, and inserted into their inner and blunter extremity: seeds as far as thirty, ovate-oblong, with a pellucid jelly about them, rufescent. It is a native of the northern parts of Europe.

Martyn remarks that the Gooseberry seems to have been formerly a fruit in very little esteem, but has received so much improvement that it is now become valuable, not only for tarts, pies and sauces, both fresh, and preserved in bottles, but as an early dessert fruit, and preserved in sugar for winter use, to answer the same purpose.

The most important varieties are of the Red kind; the hairy, smooth, deep red, damson or dark-red blueish, red raspberry, early black-red, Champagne, &c.

Of the Green kind; the hairy, smooth, Gascoigne, raspberry, &c.

Of the Yellow kind; the great oval, great

amber, hairy amber, early amber, large tawney or great mogul, &c.

Of the White kind; the common, white-veined, and large crystal.

But besides these, there is the rumbullion, large ironmonger, smooth ironmonger, hairy globe, and innumerable others, some of very large size, annually raised from seed, weighing from ten to fifteen pennyweights, but there are small ones better tasted. There are said to be upwards of two hundred, at least in name.

Mr. Forsyth gives the following list from the Catalogue of Messrs. Kirk, Nurserymen, at Brompton, near London:—

Supreme Red, Perfection Red, High Sheriff of Lancashire, Royal George, Unicorn, Rough Amber, White Walnut, Ackerley's Double Bearer, Royal Oak, Miss Bold's, Sparkler, Akerley's Rodney, Hampson's Cæsar, Monk's Charles Fox, St. John, Pigeon Egg, Worthinglowe's Conqueror, Golden Eagle, Royder's Triumph, Williamson's Yellow Hornet, Swingham, Jackson's Golden Orange, Goliath Champion, Warrington Red, Golden Drop, Costerdiner Goliath Champion, Hairy Amber, Nixon's Golden Eagle, Worthington's White Lily, Laylord's Seedling, Nixon's White Heart, Riding's Old England, Bakeley's Swingham, Tiliotson's St. John.

And he adds another "list of the largest new sorts shown in Lancashire in the summer (1800), with their colour and weight, as communicated by Messrs M'Niven, nurserymen, Manchester:—

In favourable seasons, he says, many of the above sorts have been known to weigh more by several pennyweights."

The fifth has the leaves not only wider, but of a darker colour; prickles to each leaf one or two, but sometimes none; short and much weaker than in the common Gooseberry, besides others that are harmless and much shorter scattered over the branches: the fruit when ripe commonly dark purple, but sometimes red or even yellow. It is a native of Germany, flowering in April, and the fruit ripening in June and July.

The sixth species has more frequent and milder prickles than the common Gooseberry; the leaves are smooth and more deeply cut; the fruit small and round, the size and shape of a Currant; colour at first purple, but when ripe dark purple with a blue bloom; it is smooth, on a short slender peduncle; the pulp subacid, dusky purple, with one or two brown seeds, of a round form slightly angular. The stems are ash-coloured, with frequent slender brownish prickles, like the Burnet Rose, but less rigid; the young shoots are pale green, and have green prickles: the flowers one or two from an axil, white and yellowish white. It is a native of Canada, flowering in April and May.

The seventh has the appearance of the other species, but the leaves are little gashed: the prickles like a thorn under the axils: the peduncles generally three-flowered: the germ in the flower hairy, but not prickly. It has the corolla of the third sort: the berries the size of

R I B

a hazel-nut, armed all over with stout prickles. It is a native of Canada, flowering in April.

Culture in the Currant Kind.—These may be raised with great facility from layers, seed, cuttings, &c.

In the first mode, when the trees are cut low, Mr. Forsyth advises the laying down some of the branches either in the winter or spring seasons, when the ground in the quarters or rows is dug, which should always be done annually. In the autumn following, these layers will have made fine roots; then they may be planted out where they are to stand, and they will mostly bear fine fruit in the following summer.

In the second method, the cuttings should be chosen of the strongest and straightest shoots, which should be cut six or eight inches in length, and be planted out on an east or north border, in the early autumn, at the distance of a foot from row to row, leaving only a few inches out of the ground. In this way they may be kept perfectly free from weeds. In dry weather, during the spring, they should be often refreshed with water. Some also raise these plants from suckers, but this is a method that should be avoided as much as possible, as they never grow handsome, and are apt to throw out suckers.

In respect to the seed, it should be sown on a border where the mould is fine, either in the autumn or early in the spring, and the young plants when they appear kept free from weeds. When they have attained sufficient growth they may either be planted out where they are to remain, or be set out in nursery-rows.

But Mr. Forsyth observes, that under the bushes that have been covered for late fruit, plenty of self-sown plants may constantly be found, which he advises to be planted out by themselves. And those who make currant-wine, may, he says, save the seed, after the fruit is squeezed, and dry it: it may then be sown in the manner directed above, by which, most probably, some fine varieties may be obtained. As in many gardens there still remains, the same writer says, a small sort of red and white currant not worth cultivating, he would advise those who have any of them to root them up, and plant in their room, the large red and white Dutch, the long-bunched red, and Champagne large pale red.

These plants may be planted out; Mr. Forsyth says, either in quarters or single rows round the edges of the quarters, in the gardens or other places.

And he "would particularly recommend planting a few against a south or west wall, or paling, which will produce fruit much earlier than in quarters, &c. Also to plant some be-

tween other fruit-trees on north walls, or palings, for later crops; these may be covered with double nets, to preserve them from birds; tucking in a few fern branches between the two nets, which will prevent the heat of the sun and drying winds from shrivelling the fruit. In the quarters they should be covered with mats for the same purpose; at the same time permitting all the leaves to remain on the bushes, to shade the fruit and make it keep the longer in a proper state."

In regard to the pruning of the bushes, the work may, according to the above author, "be begun in the month of November, and continued till March, as it suits the planter's convenience. And they should never be left too thick of wood; but a great deal depends on the management of them in summer, to have strong and fine wood for the following season. If they have been neglected for some years, and suffered to run up to long naked wood, they must, he says, be cut down near the ground; they will then set forth fine strong shoots. In this case, he would recommend heading down every other tree, and cutting the others partially, by taking out every other branch as near as can be to the ground, unless they are trained up with single stems, in which case it will be necessary to cut them as near as possible to where the branches begin to break out and form the head."

And "in the winter pruning, the strongest and finest shoots should be preserved, leaving them from nine to eighteen inches long, according to their strength, and from eight to ten inches apart, and as regular as possible from top to bottom of the tree; taking care to cut out all the dead and weak shoots." And "particular attention should be paid in summer, keeping the middle of the bush open to admit the sun and air; preserving the finest and strongest shoots that are nearest the stem. Some, he says, are fond of training them up with single stems, to a considerable height, to form fine round heads, which are very ornamental, if not suffered to run up too high; as in that case they are liable to be broken by the wind, if not well supported by stakes. Care must be taken not to let the shoots run to more than six inches long, because such short shoots will not be so liable to be damaged by the wind as long and weak ones are, especially when loaded with fruit. He prefers dwarfs from three to four feet high."

It is added, that "the same manner of pruning, &c., will do for Black Currants; but, as they grow stronger than the red or white, the shoots should be left thinner, and laid in longer, which will make them produce larger and finer fruit." And "those against walls and palings

should have the shoots laid in thinner than those in the quarters, and trained as horizontally as possible, shortening them in the winter pruning to a foot or eighteen inches, according to the strength of the shoots."

And as this sort of fruit "is very liable to be devoured by earwigs, which take shelter under their leaves and branches, bundles of bean-stalks should, he says, be hung up some time before the bushes are covered with mats or nets. If proper attention be not paid to this, the fruit will generally suffer very much from these insects. After the bushes are covered, take the mats off once in three or four days, and kill the earwigs that have got into the bean-stalks, which it will be necessary still to keep hung up. As there is a sweetness in the inside of beanstalks which attracts the earwigs, they very readily take shelter in them from rain. By proper attention to these directions, these destructive insects may be kept under, and the greater part of the fruit be preserved."

It is also necessary to carefully stock up all suckers at the roots of the trees, and keep them as clean as possible, otherwise they will prevent the sun and air from penetrating to the roots, and greatly weaken and injure the trees.

These plants are very liable to be infested with aphides and other insects, from which they should be freed as soon as possible, by proper picking, washing, and liming.

Culture in the Gooseberry Kind.—These are capable of being raised by cuttings and layers, as well as seeds for new varieties. They are likewise sometimes increased by suckers; but this last is not an advisable method, as the plants raised in this way are more apt to throw out suckers than those from cuttings or seed.

The cuttings should be made from the strongest and cleanest shoots, and have the length of seven or eight inches, being planted out in the early autumn, in a border which has an eastern or northern aspect, at the distance of about a foot from row to row, and having only about three or four inches of each cutting above the ground; as by this means they may be kept clean by hoeing. They require to be frequently watered in the spring season, when the weather is dry.

The layers may be laid down any time in the autumn or spring season, in the common way, when they readily strike root, and in the following autumn may be taken off and planted out where they are to remain, or in nursery rows, to get strength to be finally planted out.

The seed obtained from the ripened berries should be sown in the autumn or very early spring, in a bed of fine light mould; the

plants come up readily, and should be kept perfectly clear from weeds; and when they have had one or two years growth may be removed into nursery-rows, in the same manner as the Currants, to remain till they become fit for being planted out.

In this way good new varieties may be procured. Mr. Forsyth remarks, that the gardeners in the vicinity of Manchester have made great additions to the varieties of this fruit, and by mixing up a rich soil to plant them in, carefully watering, shading, and thinning the fruit, have brought the berries to a size much larger than had been before met with in this country; but that some of the layers are much thicker in the skin, and not so well flavoured as many of the old sorts.

The methods of planting out this sort of plants are extremely various. According to Mr. Forsyth, the market gardeners in the vicinity of the metropolis set them out in rows from eight to ten feet apart, and six from plant to plant. In cases of this sort he recommends that they should be pruned in the autumn, as about the beginning of October, when the ground between may be planted with coleworts, or beans for a spring crop; and by so doing, there will be no occasion to tread over the ground and hurt the coleworts in pruning the bushes; as before the Gooseberries begin to shoot, the coleworts will be all cleared off the ground.

And after this time (or before if you find it convenient), a good coat of rotten dung should be laid on the ground; then dig it and plant early potatoes; but not so near as to hurt the Gooseberries by their growth.

He likewise advises that the roots of Gooseberries should be kept clear to admit the sun and air. In small gardens he would recommend planting them in a quarter by themselves, at the distance of six feet between the rows, and four feet from plant to plant: they may be planted round the edges of the quarters, about three feet from the path; in which case the ground will be clear for cropping, and a man, by setting one foot on the border, can gather the Gooseberries without injuring the crop that may be on the border.

And that, as they like a rich soil, they should be dunged every year, or at least have a good coat of dung once in two years. They should never be planted under the shade of other trees, as it injures the flavour of the fruit.

In respect to the pruning of the bushes, "it is a practice too common, Mr. Forsyth says, to let them branch out with great naked stems, suffering them to remain in that state for years. When that is the case, they should be cut down

near to the ground in the winter pruning, as it will make them throw out fine strong healthy shoots, which will bear fruit the second year: and as Gooseberry-bushes, in general, bear their fruit on the second year's wood, great care should be taken in summer to keep the middle of the bush clear to admit a free air, leaving the finest and strongest shoots from six to ten inches distant from each other. This will, he says, help to ripen and harden the wood. It is a practice with some to shorten the shoots in the autumn or winter pruning, which should be always near to a wood-bud; which may be known by its being single, whereas fruit-buds are in clusters. The shoots may, he thinks, be shortened to eight or ten inches, according to their strength. Some leave them at full length for three or four years, thinning out those that are superfluous. He advises always to leave a proper number to be trained up between the full-length shoots, to succeed them when they are tired of bearing; and then to cut the old ones down to the young ones that are to succeed them. By these means the bushes may always be kept in a constant state of bearing."

Those branches which were cut the first year, will in the second throw out short dugs, or spurs, which produce the fruit; and these should by no means be cut off, unless the branches are in a sickly state, and require to be cut close down when the bushes are overloaded with fruit. "It will then, he says, be necessary to cut out a good deal of the old wood, to assist nature to recover herself after producing so great a quantity of fruit."

He advises that "great attention be paid to the cultivation of the early and late sorts. In some old gardens, in particular, there are, he says, very valuable sorts that have been of late too much neglected; he would therefore recommend to those who live in the neighbourhood of such gardens, to observe their time of ripening, and to cultivate those especially which are early and late."

He adds, that "it is a practice with some to clip the tops of Gooseberries with a pair of garden shears, as they would clip a thorn hedge; this he by no means approves of, as the fruit will not be half the size, nor of so fine a flavour, as when the bushes are kept clear of such wood as is unnecessary."

It is recommended that great "care should be taken in spring and summer to stock, or grub up, all the suckers from the roots of the bushes, leaving their stems clear and unencumbered. And as many of the Lancashire sorts are apt to grow horizontally, and the branches frequently trail on the ground, which renders them

liable to be broken by high winds, especially when they are loaded with fruit, he would recommend two or three hoops to be put round them, to which the branches may be tied, to support them, and prevent their being broken by the wind, or any other means."

When it is wished to have them very late, they should be planted on north walls and parlings, between the other trees, when they may be removed as the trees begin to meet. If laid in thin, they will bear very fine and handsome fruit. He would advise to plant the finest late sorts; as by this method the table will be supplied much longer than by the common custom of planting in quarters of the garden.

And "immediately after pruning, he always applies the Composition to the ends of the shoots and cuttings; and he finds it of great use in preventing the exhalation of the sap, and preserving the cuttings till they take root and become established."

These sorts of plants are very much infested with a small green caterpillar, which frequently devours both leaves and fruit: great attention is of course necessary to observe their first appearance on the bushes; as, if not destroyed early, they increase so fast, that they soon devour all the leaves, and the fruit is good for nothing. It is observed, that "they first appear generally on the edges and under-sides of the leaves."

In order to destroy them, he advises to "take some sifted quick-lime and lay it under the bushes; but not at first to let any of it touch the branches or leaves; then shake each bush suddenly and smartly, and the caterpillars will fall into the lime; if the bush be not shaken suddenly, the caterpillars, on being a little disturbed, will take so firm a hold as not easily to be shaken off. After this is done, some of the lime should be sifted over the bushes; this will drive down those which may have lodged on the branches. The caterpillars ought, he says, to be swept up next day, and the bushes well washed with clear lime-water mixed with urine; this will destroy any caterpillars that may still remain, and also the aphides, if there are any on the bushes at the time."

Forcing.—Sometimes trees of the gooseberry and currant kinds are forced for early fruiting, by means of artificial heat in fruit-forcing-houses, hot-walls, or forcing-frames, &c. For this purpose, some young trees should be planted in largish pots, one plant in each, and being advanced to a full state of growth for plentiful bearing, should be introduced in any of the above forcing departments that are in work by fire, or hot-bed heat, or both, in forwarding

any principal sorts of fruit-trees, plants, or flowers, at the proper season, as about January or February, in which the same culture, in regard to the degree of heat, and other requisites, necessary for the other trees, &c., is suitable for these. Water should be given occasionally to the earth in the pots, and sometimes after the fruit is set, throwing it lightly over the branches on a warm sunny day; and they will thus produce ripe fruit in April or the following month.

The forcing of this sort of fruit is now however seldom much attended to.

RICINUS, a genus containing plants of the tall herbaceous tender annual kind.

It belongs to the class and order *Monocotyledon*, and ranks in the natural order of *Tricocceae*.

The characters are: that in the male the calyx is a one-leaved, five-parted perianth: segments ovate, concave: there is no corolla: the stamina have very numerous filaments, filiform, branching collected below into various bodies: anthers two, roundish:—females on the same plant: the calyx is a one-leaved perianth, three-parted: segments ovate, concave, deciduous: there is no corolla: the pistillum is an ovate germ, covered with subulate corpuscles: styles three, two-parted, from erect spreading, hispid: stigmas simple; the pericarpium is a roundish capsule, three-grooved, prickly all over, three-celled, three-valved: the seeds solitary, subovate.

The species cultivated is *R. communis*, Common Palma Christi.

It rises with a strong herbaceous stalk to the height of ten or twelve feet; the joints are at a great distance from each other; the stalk and branches are of a gray colour; the leaves large, and on long footstalks; deeply divided into seven lobes, and are gray on their under side. The flowers are disposed in long spikes, which spring from the division of the branches: the males are placed on the lower part of the spike; the females, which occupy the upper part, have prickly calyxes: the root is biennial, long, thick, whitish, and beset with many small fibres. It is a native of the Indies, flowering here in July and August.

It becomes a tree in its native situation, and the seeds afford the castor oil of the shops.

There are several varieties, as the Great American Palma Christi, which has brown stalks that divide into two or three branches, and rise six or seven feet high; the leaves are broader, and not so deeply divided; they are of a deep green on both sides, and are unequally serrate. The spikes of flowers are shorter, the seed-vessels rounder and of a brownish colour, and

R I C

the seeds are much less, and brown. It is a native of the West Indies.

The Green-stalked American Palma Christi, which has a thick herbaceous stem, of a grayish green, with the joints not so far asunder as in the preceding sorts: it rises about four feet high, and is divided at the top into three or four branches, which spread out almost horizontally: the leaves are large, of a deep green on their upper side, but grayish on their under; they are deeply cut into six or seven (sometimes eight) lanceolate segments, which are unequally serrate: the petioles spread out more horizontally than those of the common sort, and are much shorter: the principal stalk and branches are terminated by loose spikes of flowers: the covers of the capsules are green, and closely armed with soft spines: the seeds are smaller and lighter coloured than those of the preceding. It is also a native of the West Indies.

The Wrinkled-capsuled Palma Christi, which rises with an herbaceous stalk about four feet high: the lower part is purplish, and the upper deep green, the joints pretty far asunder: the leaves are of a deep green on their upper side, but paler underneath; they are not so deeply divided as some of the others, and are more regularly serrate: the spikes of flowers are large: the males have more stamens, with yellow anthers: the capsules are oval and wrinkled, but have no prickles: the seeds are small and brown. It is a native of both Indies.

The Red-stalked Palma Christi, which rises with a large reddish stalk to the height of ten or twelve feet, with many joints, and dividing into several branches: the leaves are very large, some measuring more than two feet and a half in diameter; are of a dark green, unequally serrate, and not so deeply cut as in some of the varieties: the spikes of flowers are large, and brown, with whitish anthers: capsules large, oval, and closely set with soft prickles: the seeds are very large, and beautifully striped. It is a native of Africa and both Indies.

The Small American Palma Christi, of which there are two sub-varieties, one with a red, the other with a pale-green stalk, distinguished in America by the names of Red and White Oil-seed: the stems seldom rise more than three feet high, sometimes dividing at the top into two or three branches: the leaves are much smaller and more deeply divided than in the other varieties; their borders are unequally serrate, and the segments of the leaves are frequently cut on the sides: the spikes of flowers are smaller and more compact: the capsules are also smaller, rounder, of a light green, and closely set with soft prickles:

R I D

the seeds small, and finely striped. It is a native of Carolina, &c.

The Livid-leaved Palma Christi, which is an evergreen tree, ten feet in height, and more: the trunk, during the first year, is blood-red and very shining; afterwards it becomes woody, as thick as the wrist, hollow with transverse septa, pithy, with circular warts at the joints from fallen stipules, ash-coloured, interruptedly and slightly streaked: before the leaves come out, they are wrapped up in red stipules like sheaths, that fall off soon after: the leaves are divided half way into eight, sometimes ten lobes, which are serrate and acute, and the petiole is long; they are of a dark blood-red colour on the upper surface, and livid on the lower, with blood-red veins, the largest less than a foot in diameter, quite smooth, without any hairiness whatever: the fruit of a livid colour, with long soft prickles: the seeds shining, variegated with black and brown. It is a native of the East Indies.

Culture.—These plants are capable of being increased by seeds, which should be sown upon a hot-bed in the spring, and when the plants are come up, be each planted into a separate pot filled with light fresh earth, and plunged into a fresh hot-bed, watering and shading them until they have taken root; after which they must have a great share of free air when the season is mild, otherwise they draw up tall and weak. As the plants grow fast, and their roots in a short time fill the pots, they should be shifted into larger pots, filled as above; and about the end of May, when the season is warm, be hardened to endure the open air by degrees; when, if some of the plants be shaken out of the pots, and planted out into a very rich border, and in dry weather duly watered, they grow to a large size, and produce a great quantity of flowers and seeds. If it be intended to preserve any of the plants through the winter, they must not be planted out in the full ground, but be shifted into larger pots occasionally, as their roots require, placing them in the open air during the summer season in some warm situation, where they may remain until October, when they must be removed into the green-house with other exotic plants, watering them sparingly in winter, and admitting free air in mild weather, as they only require to be protected from frost and cold winds.

They have a fine ornamental effect in their leaves among other potted green-house plants, and also in the large open border or clumps, when cultivated as annuals, but they require room.

RIDGING OF GROUND, the practice of

throwing it up into high ridges, in order to lie fallow in winter, &c., to mellow, and improve in its quality and fertility.

This is work of great utility in the kitchen garden, as well as in other parts, but more especially in stiff and heavy soils, and cold wet lands. It is accomplished by trench-digging the ground over, laying the earth of each trench in a raised, rough ridge, lengthways, that by thus lying as high, open and hollow, as possible, it may meliorate and fertilise more effectually by the weather during the winter. And it receives further improvement from the levelling it down again, which is expeditiously effected, for the reception of the intended seeds, plants, roots, &c., which breaks, divides, and pulverises the earth still more effectually.

This ridging is generally performed either in the latter end of autumn, or any time in winter, or early in the spring, as the ground is the most vacant at those seasons, and not generally immediately wanted for any principal sowing or planting.

This sort of work is executed by beginning at one end of the plat of ground, and digging out a trench one or two spades in width, and a full spade's depth, removing the crumbs from the bottom, in the length-ways across the ground, and wheeling the earth to the finishing end, to be ready to fill up the last trench: so marking out a second trench close to the first, of the same width, then proceeding in the trenching and ridging, previously paring the top of the second trench, with all weeds, rubbish, or dung thereon, if any, into the bottom of the first, and then digging the ground of the second along regularly, the proper width and depth as above; turning the earth spit and spit into the first open trench, laying it in a raised ridge lengthways thereof, without breaking it fine, so that it may lie somewhat rough and hollow, according as the nature of the soil may admit: proceeding thus with another trench in the same manner, and continuing the same with the whole, trench and trench, to the end of the plat of ground; filling up the last trench with the earth of the first opened, laying it now ridge-ways as in the preceding trenches.

In the work of levelling down ridged ground, as wanted, it should proceed regularly, ridge and ridge, long-ways, levelling the earth equally to the right and left, loosening any solid parts, and breaking all large rough lumps and clods moderately fine; forming the whole in an even regular surface, in order for sowing and planting as required.

And in general, it is not advisable to lay down more than can be sown the same or next day,

while the surface is fresh stirred, especially in broad-cast sowing and raking in the seed, as most generally all tolerably light mellow soils are more yielding to the rake while the surface is fresh moved; or before rendered wet by rain, &c., or very dry and hardened in the top earth by the sun, air, and winds, in dry weather, in the spring months, &c., and likewise, for sowing seeds by bedding in and covering in with earth from the alleys, &c., or with earth raked off the beds for that purpose, it would generally be most successful to perform it in a fresh stirred surface; though it is not so material in drill sowing: and besides, when seeds are committed to the earth while it is in a fresh turned up surface, especially in a dry season, they are more forwarded in a free regular germination than in ground that has lain some time after digging or levelling down. Though some grounds of a wet, or heavy, stiff nature, sometimes require to lie a few days after digging or levelling down, in order for the rough cloddy surface to mellow in some degree, either by drying a little, or by having a moderate rain, or sometimes both, to meliorate the lumpy clods, pliant to the rake, in the case of broad-cast sowing and raking in the seed.

RIVINA, a genus containing plants of the shrubby evergreen kind.

It belongs to the class and order *Tetrandria Monogynia*, and ranks in the natural order of *Holoraceæ*.

The characters are: that the calyx is a four-leaved perianth, coloured, permanent: leaflets oblong-ovate, blunt: there is no corolla, unless the calyx be taken for it: the stamina have four or eight filaments, shorter than the calyx, approaching by pairs, permanent: anthers small: the pistillum is a large germ, roundish: style very short: stigma simple, blunt: the pericarpium is a globular berry, placed on the green reflex calyx, one-celled, with a point curved in: the seed one, roundish, lens-shaped, rugged.

The species cultivated are: 1. *R. humilis*, Downy Rivina; 2. *R. lavis*, Smooth Rivina; 3. *R. octandra*, Climbing Rivina.

The first grows taller than the second, and the branches are more erect: the leaves are smaller, heart-shaped, and covered with short hairy down: the spikes of flowers are not so long; the flowers are not so closely placed together, and have longer peduncles. It is a native of the West Indies.

The second species rises with shrubby stalks six or eight feet high, dividing into several spreading branches, and covered with a gray spotted bark: the leaves alternate, lanceolate, entire, two inches and a half long and one inch

broad in the middle, drawing to a point at each end, smooth, of a lucid green, and pretty thick consistence, on long slender footstalks, and placed at pretty great distances on the branches: the flowers in long bunches, from the side and at the end of the branches, each on a slender peduncle near half an inch long: calyx scarlet: stamens eight, longer than the calyx: berry roundish, with a thin pulp, outwardly scarlet changing to purple; inclosing one roundish hard seed. It resembles the preceding very much, but is wholly smooth; but the leaves are purplish about the edge, and the flowers red on the outside. It is a native of the West Indies, flowering most part of the year.

The third rises with a climbing woody stalk to the height of twenty feet, covered with a dark gray bark: the leaves are oval-lanceolate, near three inches long, and an inch and half broad, smooth, entire, on short footstalks: the flowers come out in long bunches from the side of the branches, shaped like those of the second sort. The berries are blue, of the same size with those of the other. It is a native of the West Indies.

Culture.—These plants may be increased by seeds procured from the places where they are natives, sowing them as soon as they are obtained, in pots filled with fresh light earth, plunging them in a hot-bed when in summer, but in the tan-bed of the stove in the autumn or winter. The earth should be well moistened during the summer season, but very sparingly in the winter. They should be carefully preserved in these situations till the seeds vegetate, which is often a great length of time, of course the pots should not be disturbed.

When the plants have attained about two inches in growth, they may be removed into separate small pots, filled with light loamy mould, plunging them into a hot-bed, shading them till fresh rooted.

They afterwards require the management of other stove exotic plants.

They may likewise sometimes be raised by layers and cuttings, assisted by the heat of the bark hot-bed.

After these plants have been preserved in the stove of the hot-house till they have attained a good growth and strength, they are capable of being preserved in moderate warmth in winter, and in the warmest part of summer in the open air, in a warm sheltered place.

They afford variety among other potted ever-green stove plants.

ROBINIA, a genus comprising plants of the hardy deciduous tree and shrub sorts, with tender kinds for the stove.

It belongs to the class and order *Diadelphix Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved perianth, small, bell-shaped, four-cleft: the three lower toothlets more slender; the upper fourth toothlet wider, scarcely emarginate to the naked eye, all equal in length: the corolla papilionaceous: standard roundish, larger, spreading, blunt: wings oblong, ovate, free, with a very short blunt appendix; keel almost semiorbicular, compressed, blunt, the length of the wings: the stamina have diadelphous filaments, (simple and nine-cleft) ascending at top: anthers roundish: the pistillum is a cylindrical, oblong germ: style filiform, bent upwards: stigma villose in front at the top of the style: the pericarpium is a legume large, compressed, gibbous, long: the seeds few, kidney-form.

The species cultivated are: 1. *R. Pseud-Acacia*, False or Common Acacia; 2. *R. hispida*, Rose Acacia, or Robinia; 3. *R. Caragana*, Siberian Abrupt-leaved Robinia; 4. *R. frutescens*, Shrubby Robinia; 5. *R. pygmaea*, Dwarf Robinia; 6. *R. spinosa*, Thorny Robinia; 7. *R. violacea*, Ash-leaved Robinia; 8. *R. mitis*, Smooth Indian Robinia.

It grows very fast whilst young, so that in a few years from seed, the plants rise to eight or ten feet high, and it is not uncommon to see shoots of this tree six or eight feet long in one summer: the branches are armed with strong crooked thorns: the leaflets eight or ten pairs, ovate, bright green, entire, sessile: the flowers come out from the side of the branches in pretty long bunches, hanging down like those of *Laburnum*: each flower on a slender pedicel, white, and smelling very sweet: they appear in June, and when the trees are full of flowers, make a fine appearance and perfume the air round them; but they seldom continue more than a week. It is a native of North America, where it grows to a very large size, and the wood is much valued for its duration.

There is a variety which has no thorns on the branches, but which is easily known at first sight by its peculiar appearance.

And the Echinated, or Prickly-podded American False Acacia, in which the pods are much shorter, and closely beset with short prickles, but in other respects agrees with the common sort.

The second species rises in its native situation sometimes to the height of twenty feet, but in this climate seems to be of low growth; the branches spread out near the ground, and produce their flowers very young: the young branches, and also the peduncles and calyxes are

closely armed with small brown prickles, or rather stiff bristly hairs, like raspberries and some sorts of roses; the leaves are like those of the first sort, but the leaflets are larger and rounder; the flowers are larger, and of a deep rose colour, but they have no scent: they come out early in June, and make a fine appearance; each flower is on a short separate pedicel: the legumes flat oblong. It is a native of Carolina.

The third has arboreous trunks, commonly branched from the bottom, slender, with a smooth, shining, coriaceous bark, covered by a greenish ash-coloured skin: branches alternate, very much divided; twigs rod-like, weak, very leafy, ash-coloured or greenish, with longitudinal nerves running from bud to bud: buds alternate, frequent, bearing both leaves and flowers, unarmed, with the stipules of the bud-leaves soft, but in the new branches spinescent, divaricating, rigid. It is a native of Siberia, flowering in April and May.

The fourth species has a branched trunk from the bottom, with a dusky or greenish-ash-coloured bark; there are commonly many lateral shoots or suckers from the root: the branches rod-like, pliant, loaded with leaves and flowers, of a shining yellowish colour, with longitudinal gray nerves, with triple spines: the leaves on the shoots of the year alternate, with spinescent stipules; from the buds in bundles, with unarmed stipules: the leaflets clustered, obovate, attenuated at the base, with a spinule at the end: petiole spinescent, after the leaves are fallen, hardening with the stipules into a triple spine: the peduncles on the branches of the preceding year from each bud, one, two, or three, bent a little at the joint, one-flowered. It is a native of Siberia, by the Volga, &c.

The fifth has trunks covered with a shining yellowish bark: wood of a very deep bay, almost as hard as horn: the older twigs round, with a beautifully golden shining cuticle; branchlets gray, with very frequent two-spined buds: the spinules slender like needles, spreading, arising from the stipules, in the older branches deciduous: the leaflets four or six in the spontaneous shrub clustered in bundles, quite sessile, linear acuminate, a little hispid: the peduncles springing singly from most of the buds on the branchlets among the leaves, the length of the leaflets, bent at the joint. In this climate it is a low shrub, seldom rising more than three feet. The flowers are yellow, and appear in April. It is a native of Siberia.

The sixth species resembles the third sort, but is distinguished by its stiff or thorny stipules: it is a shrub above the height of a man: the leaflets six or eight, ovate, even; common petiole

VOL. II.

woody, the whole of it perennial, thorny at the end: the stipules awl-shaped, thorny, perennial: the trunk is scarcely an inch and half in diameter, with branches often a fathom in length, subdivided, twisted and diffused, so as to form a hemispherical head, full of branches and thorns. Being covered with flowers during the whole summer, it appears very beautiful: the wood bay-coloured within, on the outside yellow, and very hard: the cuticle on the younger branches greenish yellow, less shining, and more strigose than in the fifth sort, with ash-coloured longitudinal nerves, running from branch to branch: the branches are round, divaricating, alternate: the thorns spreading out every way almost at right angles, alternate, very large, arising from the permanent petioles enlarged, marked also with the scars of the leaflets, and having at the base on each side a small, bristle-shaped spinule, standing up, and arising from the stipules: there are several leaves and two or three flowers from the axils of all the spines on the branches: the petioles are spinescent: the leaflets commonly two pairs, but sometimes three and even four, linear-lanceolate, mucronate at the end with a spinule, opposite and remote: the peduncles are so short that the flowers seem to be sessile. It is a native of Siberia.

On account of the length and toughness of the branches, and its large stout thorns, it is admirably adapted to form impenetrable hedges, and is sufficiently hardy to bear our climate.

The seventh is an upright tree without thorns, growing to the height of twelve feet: the leaves alternate, numerous, shining; having three leaflets on each side, sometimes two, very seldom five; these are ovate, blunt, emarginate, entire, petioled, opposite, two inches long: the racemes axillary, half a foot in length; pedicels short, two-flowered, numerous: the flowers have the smell and colour of violets. It is a native of Carthage.

The eighth species has a shrubby stem, three feet high, upright, branched: the leaflets ovate-lanceolate, smooth, bright green, two- or three-paired: the racemes terminating, short: the corolla yellow: the legume oblong, narrowing to each end, smooth: the branches round, unarmed: the leaflets five, ovate, smooth, quite entire: the racemes have three flowers fixed at each tooth, each on its proper pedicel: the calyx subtruncate. It is a native of the East Indies, &c.

Culture.—The first six hardy sorts are all capable of being raised from seeds, cuttings, layers, and suckers; but the seed method is said to afford the best plants.

The seeds should be sown about the end of March or beginning of the following month, on a bed of light mould, being covered to the depth of about half an inch. In the first sort and varieties the plants mostly appear in the course of six or eight weeks; but in the other kinds often not till the next spring. They should be well weeded and watered, and when sufficiently strong be set out in the spring or autumn in nursery-rows, for two or three years, in order to remain to have proper growth for final planting out.

The cuttings should be made from the young shoots, and planted out in the beginning of autumn, in a shady border where the soil is mellow. They are mostly well rooted in the course of a twelvemonth, when they may be removed into nursery-rows as above.

The layers should be made from the young wood, being laid down in the autumn, when in the course of the year they mostly become well rooted, and may be taken off and planted out in nursery-rows as the seedling plants.

The suckers, which are produced in plenty from the two first sorts, which may be removed in the early autumn or spring, and planted out in nursery-rows or in beds, to be afterwards removed into them.

The two last, or tender sorts, may likewise be raised from seeds and cuttings, but they must be sown and planted in pots, filled with good mould, to have the assistance of a hot-bed in the stove, by being plunged in it. When the plants have attained a little growth, they should be shaken out of the pots, and planted separately in small pots, filled with the same sort of earth, plunging them in the tan-bed, affording due shade till well rooted, managing them afterwards as other tender stove plants.

The plants are most tender while young; they should therefore be kept in the stove tan-bed till they have acquired strength, when they may be preserved in the dry stove, with a temperate heat in winter, and be exposed in the open air in summer, in a warm sheltered situation when the weather is fine.

The hardy sorts have a fine effect in the border clumps and other parts of pleasure-grounds, and the tender kinds afford variety in the stove collections.

ROBINSON CRUSOE'S COAT. See **Cactus**.

ROCANBOLE. See **ALLIUM**.

ROCK-ROSE. See **Cistus**.

RONDELETIA, a genus containing plants of the woody exotic stove kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Rubiaceae*.

The characters are: that the calyx is a one-leaved perianth, superior, five-parted, acute, permanent: the corolla one-petalled, funnel-shaped: tube cylindrical, longer than the calyx, bellying a little at top: border five-parted, from reflex flat; segments roundish: the stamina have five awl-shaped filaments, almost the length of the corolla: anthers simple; the pistillum is a roundish, inferior germ: style filiform, the length of the corolla: stigma bifid: the pericarpium is a roundish capsule, crowned, two-celled: the seeds several, or sometimes solitary.

The species chiefly cultivated is *R. Americana*, American *Rondeletia*.

It rises with a woody stalk ten or twelve feet high, branching out on every side; the branches covered with a smooth greenish bark: the leaves are oblong, ending in acute points, entire, the upper surface lucid green, the under pale; they are a little crumpled, and stand alternate: the flowers come out in bunches at the end of the branches, are white, and have little scent. They appear in autumn, but are not followed by seeds in this climate.

Culture.—This plant may be increased by sowing the seeds on a moderate hot-bed in the early spring, and when the plants have attained a little growth they should be removed into separate pots, being plunged in the bark-bed of the stove, where they are to remain and be managed as other tender exotic plants of a similar kind.

They afford variety in stove collections.

ROSA, a genus containing plants of the deciduous flowering shrub and evergreen kind.

It belongs to the class and order *Icosandria Polygynia*, and ranks in the natural order of *Sciticeae*.

The characters are: that the calyx is a one-leaved perianth: tube ventricose, contracted at the neck; with the border spreading five-parted, globular: segments long, lanceolate-narrow (in some of them two alternate ones appendicled on both sides; two others, also alternate, naked on both sides; the fifth appendicled on one side only): the corolla has five petals, obcordate, the length of the calyx, inserted into the neck of the calyx: the stamina have very many filaments, capillary, very short, inserted into the neck of the calyx: anthers three-cornered: the pistillum has numerous germs, in the bottom of the calyx: styles as many, villose, very short, compressed close by the neck of the calyx, inserted into the side of the germ: stigmas blunt: there is no pericarpium: is a fleshy berry, turbinate, coloured, soft, one-celled, crowned with the rude segments, contracted at the neck,

formed from the tube of the calyx: the seeds numerous, oblong, hispid, fastened, to the inner side of the calyx.

The species cultivated are: 1. *R. lutea*, Single Yellow Rose; 2. *R. sulphurea*, Double Yellow Rose; 3. *R. flanda*, Hudson's-Bay Rose; 4. *R. cinnamomea*, Cinnamon Rose; 5. *R. arvensis*, White Dog Rose; 6. *R. pimpinellifolia*, Small Burnet-leaved Rose; 7. *R. spinosissima*, Scotch Rose; 8. *R. parviflora*, Small-flowered American Rose; 9. *R. lucida*, Shining-leaved American Rose; 10. *R. Carolina*, Carolina Rose; 11. *R. villosa*, Apple Rose; 12. *R. provincialis*, Provence Rose; 13. *R. centifolia*, Hundred-leaved Rose; 14. *R. Gallica*, Red Rose; 15. *R. damascena*, Damask Rose; 16. *R. sempervirens*, Evergreen Rose; 17. *R. pumila*, Dwarf Austrian Rose; 18. *R. turbinata*, Frankfort Rose; 19. *R. rubiginosa*, Sweet Briar Rose; 20. *R. muscosa*, Moss Provence Rose; 21. *R. moschata*, Musk Rose; 22. *R. alpina*, Alpine Rose; 23. *R. semperflorens*, Deep-red China Rose; 24. *R. alba*, White Rose.

The first has weak stalks, which send out many slender branches closely armed with short crooked brown prickles: the leaflets two or three pairs, ovate and thin, smooth, of a light green, sharply serrate: the flowers on short peduncles, single, bright yellow, without scent. It is a native of Germany, &c.

There is a variety termed the *Austrian Rose*, which has the stalks, branches and leaves like those of the Single Yellow Rose, but the leaves are rounder. The flowers are also larger; the petals have deep indentures at their points; are of a pale yellow on the outside, and of a reddish copper colour, orange-scarlet, or Barré colour within; are single, have no scent, or a disagreeable one, and soon fall away. It has sometimes flowers entirely yellow on one branch, and copper-coloured on another.

The second species differs from the preceding, not only in the doubleness of the flowers, but in having the leaflets simply serrate, not glandular, pubescent and glaucous underneath; whereas in that they are doubly serrate, glandular and glutinous, and of a shining green colour, the stipules lacerated; the fruits hemispherical and glandular, which in the other are subglobular and smooth: the prickles on the stem are of two sorts in this; a few being larger, and many smaller. It is a native of the Levant, flowering later than that, as in July.

The third has the stems, when full grown, unarmed; the younger ones, or those of the first year, are armed with slender straight prickles bent a little back at the top: branches round, unarmed, shining, reddish: the leaflets

commonly seven, oblong, sharply and almost equally serrate, smooth: the petioles smooth, generally armed with one or two spinules. It is a native of Newfoundland and Hudson's Bay, flowering from May to August.

The fourth species rises about four feet high: the branches are covered with a purplish smooth bark, and have no spines, except at the joints immediately under the leaves, where they are commonly placed by pairs; they are short and crooked: the leaflets seven, ovate, serrate, hairy on their under side: the leaves of the calyx narrow and entire: the flower small, with a scent like cinnamon, whence its name. But, according to Parkinson, the shoots are somewhat red, yet not so red as the double kind, armed with great thorns, almost like the Eglantine bush; thereby showing, as well by the multiplicity of its shoots as the quickness and height of its shooting, its wild nature: the roses are single, somewhat large, and of a pale red colour. It is a native of the South of Europe.

There is a double variety, in which the shoots are redder; the flowers small, short, thick, and double, of a pale red colour at the end of the leaves (petals), somewhat redder and brighter towards the middle. It is the smallest and earliest of the double garden roses, flowering in May.

The fifth has round, glaucous, often mahogany-coloured stems; with very long, thong-like branches, bowing, with scattered, hooked prickles, smaller than in the common Dog-Rose: the leaflets five or seven, but mostly five, ovate, pointed, smooth, simply serrate, glaucous underneath: the petioles prickly: peduncles three or five in a terminating cyme, (rarely solitary) mahogany-coloured, covered with a glandular roughness, not all exactly from one point, accompanied by a few lanceolate bractes, and each bearing a single white flower, like the common Dog-Rose, but never red or blush-coloured, and less fragrant: fruit oblong; but in ripening it becomes globose, and deep red: the styles, as soon as they have passed through the neck of the calyx, are compacted into a cylinder, resembling a single style, terminated by a knob composed of the stigmas, which distinguishes it from the other species. It is a native of England, &c.

The sixth species has been confounded with what is commonly called the Scotch Rose; and some think it is not distinct from that. In the garden plant, according to Pallas, there are larger and setaceous prickles intermixed, and nine leaflets, the lower ones smaller. The flowers are white, and the segments of the calyx entire.

And the Siberian shrub is very elegant, a foot and half or at most two feet in height; the trunk thorny all over, the thickness of the little finger, very much branched, the branches collected into an ovate form: the spines on the trunk and branches very frequent, bristle-shaped, transverse or reclining, gray: the leaves very small, on red petioles, sometimes smooth, sometimes with small prickles on them: the stipules very narrow with wider earlets, external and serrate: the leaflets commonly seven, but sometimes nine or five, the size of the little finger nail, oval, cut round, sharply double-serrate, stiffish, rugged, more or less retuse, on some shrubs rather acute: the peduncles sometimes rough, sometimes smooth, with a ternate and simple leaf, almost to the flower: the fruit globose, smooth, and when ripe black, dry and insipid, being crowned with the segments of the calyx. It is a native of the South of Europe, as well as Asia, flowering here in May and June.

The seventh has its stems about two feet high, upright, much branched, with numerous straight, unequal, very slender needle-like prickles, on the young branches, which often disappear from the old ones: the leaflets seven or nine, small, roundish, blunt, serrate, smooth, sessile: their common petiole is sometimes prickly: the peduncles solitary, one-flowered, smooth, or very seldom prickly: the stipules small, half-belt-shaped, toothed: the tube of the calyx almost hemispherical, smooth: the segments are entire: the petals white or cream-coloured, yellow at the base, delicately fragrant, sometimes striped with red: the fruit globose, deep red, black when quite ripe, smooth, but sometimes somewhat prickly. It is a native of most parts of Europe.

There are several varieties, as the Striped-flowered, or with variegated flowers, red striped with white.

The Red Scotch Rose, which seldom rises more than a foot high: the stalks are covered with a brown bark, and are closely armed with small spines; the leaves are very small; the flowers are also small, sessile, and of a livid red colour: the fruit is round, of a deep purple colour inclining to black when ripe.

And, according to Withering, there is also a variety with prickly peduncles, and cream-coloured flowers, changing to white.

Lawrence likewise mentions a double Scotch Rose.

The eighth species very much resembles the two following sorts; but differs in having the stem two feet high, the petioles hairy at the top, and the flowers in pairs. It rises with several slender stems to the height of two or three feet,

covered with a brownish-green bark, and armed with a few sharp spines: the leaflets are seven or nine, oblong-ovate and sharply serrate: the leaves of the flower-cup have often linear leafy elongations: the corolla is single and of a pale reddish colour.

There is a variety with a double flower.

The ninth rises with several smooth stalks to the height of five or six feet: the young branches are covered with a smooth purple bark: the leaves are composed of four or five pairs of spear-shaped leaflets, smooth on both sides, of a lucid green on the upper surface, but pale on the under, and deeply serrate: the segments of the calyx long, narrow and entire: the flowers of a livid red colour, single, with little scent, appearing in July.

The tenth species has the stem five or six feet high, smooth: the stipular prickles two: the leaflets seven, oblong-ovate or nearly lanceolate, smooth, not shining, but opaque, serrate, paler underneath: the petioles prickly: the peduncles several, branched, forming a corymb, unarmed, with glandular hairs scattered over them: the leaflets of the calyx undivided, hispid on the outside: the petals obcordate, red. It is a sort that flowers late; and, like the two preceding, a native of North America.

The eleventh grows upright to the height of four feet or more: the branches are upright and short: the prickles on the stem and branches scattered, small, awl shaped, nearly straight: the leaflets seven, elliptical, bluntish, clothed on both sides with short velvet-like down, fragrant when rubbed, their serratures fringed with glands: the petioles downy, prickly, glandular: the peduncles terminating, mostly solitary, one-flowered, rough with rigid glandular bristles: the germ globular, bristly: the segments of the calyx long, downy, prickly on the outside: the corolla of a full rose-colour, not very odoriferous: the fruit globular, larger than in any other sort, and for the most part bristly and blood-red. It is found in Europe and Asia, and known as a cultivated sort in plantations, &c., both in a single and double state.

The fruit has a pleasant acid pulp surrounding the seeds, and is sometimes made into a conserve or sweetmeat, and served up at table in desserts, &c.

The twelfth species is well known in gardens, and one of the most beautiful sorts: the flowers are sometimes very large, and the petals closely folded over each other, like cabbages, whence it is called the Cabbage Rose: the flowers have the most fragrant odour of all the sorts.

According to Parkinson, the Great Double

Damask Provence, or Holland Rose, has its bark of a reddish or brown colour: the leaves likewise more reddish than in others, and somewhat larger. It usually grows very like the Damask Rose, and much to the same height: the flowers are of the same deep blush colour, or rather somewhat deeper, but much thicker, broader, and more double by three parts almost, the outer leaves turning back, when the flower hath stood long blown, the middle part itself being folded hard with small leaves: the scent comes nearest the Damask Rose, but is much short of it.

There are several varieties, as the **Red Provence Rose**: the stem and branches are not so great as those of the other, but greener, the bark not being so red: the flowers are not so large, thick and double, but of a little deeper damask or blush colour, turning to red, but not coming near the full colour of the best Red Rose: nor is the scent so sweet as that of the Damask Provence, but coming near that of the ordinary Red Rose. It is not so plentiful in bearing as the Damask Provence.

The **Blush Provence Rose**, in which the stalks rise from three to four feet high, and are unarmed: the leaves are hairy on their under side: the peduncles have some small spines: the segments of the calyx are semi-pinnate: the corolla has five or six rows of petals, which are large, and spread open; they are of a pale blush colour, and have a musky scent.

The **White Provence Rose**, which differs only in the colour of the flowers.

The **Great and Small Dwarf Provence Roses**, called *Rose de Meaux*, differ from each other in little except size: the smaller of the two is generally known by nursery-men and gardeners by the name of *Pomponne Rose*. It throws out numerous stems, which rarely exceed a foot or a foot and half in height; usually straight, rigid, and very prickly: the flowers very small, and distinguished by the brilliant colour of the central petals, appearing in June.

All the sorts flower from July to August.

The thirteenth rises with prickly stalks about three feet high: the leaves have three or five leaflets, which are large, oval, smooth, and of a dark green with purple edges: the peduncles are set with brown bristly hairs: the segments of the calyx are smooth and semipinnate: the flowers are very double, and of a deep red colour, but have little scent. It is a native of China.

The varieties are very numerous; as the **Dutch Hundred-leaved Rose**; the **Blush Hundred-leaved Rose**; the **Singleton's Hundred-leaved Rose**.

The **Single and Double Velvet Rose**, which, according to Parkinson, has the old stem covered with a dark-coloured bark, but the young shoots of a sad green, with few or no thorns: the leaves are of a sadder green than in most roses, and very often seven on a stalk: the flower is single; or double with two rows of petals, the outer larger, of a deep red like crimson velvet; or more double, with sixteen petals or more in a flower, most of them equal: they have all less scent than the ordinary red Rose.

The **Burgundy Rose**, which is an elegant little plant, not more than a foot or eighteen inches in height.

The **Sultan Rose**; the **Stepney Rose**; the **Gurnet Rose**; the **Bishop Rose**; and the **Lisbon Rose**.

The fourteenth species has the stalks growing erect, and scarce any spines; they rise from three to four feet high: the leaves are composed of three or five large oval leaflets, which are hairy on their under side: the leaves of the calyx are undivided: the flowers are large, but not very double, spread open wide, and decay soon; they are of a deep red colour, and have an agreeable scent. "Parkinson gives the Red Rose the epithet of English, as this and the White are the most antient and known Roses to the country, and assumed by our precedent kings of all others, to be cognizances of their dignity, and because the Red is more frequent and used in England than in other places. The flowers, he says, vary in colour; some are of an orient red or deep crimson colour, and very double, although never so double as the White; some again are paler, tending somewhat to a damask; and some are of so pale a red, as that they are rather the colour of the Canker Rose; yet all for the most part with larger leaves than the damask, and with many more yellow threads (stamens) in the middle: the scent is much better than in the White, but not comparable to the excellency of the Damask Rose; yet this, being well dried and kept, will hold both colour and scent longer than the Damask."

There are several varieties: as the **Red Official Rose**; the **Mundi Rose**, which has the flowers very elegantly striped or variegated with red and white; in other circumstances it so perfectly resembles the Red Rose, that there can be no doubt of its being a variety of that; indeed it frequently happens that a Red Rose or two appears on the same plant with the variegated flowers.

The **Childing Rose**, the **Marbled Rose**, and the **Double Virgin Rose**, which have great affinity with each other, according to Miller.

The fifteenth rises with prickly stalks eight or ten feet high, covered with a greenish bark, and armed with short prickles: the leaves are composed of five or seven oval leaflets, dark green above, but pale underneath; the borders frequently turn brown and are slightly serrate; the peduncles are set with prickly hairs; the calyxes are semipinnate and hairy; the corolla is of a soft pale red, and not very double, but has an agreeable odour; the hips are long and smooth. It is a native of the South of France, &c.

There are several varieties: as the Red Damask Rose, the Blush Damask Rose, which differ only in the shade of colour.

The York and Lancaster Rose, which agrees with the Damask in stalk, leaf, &c., differing only in the flower being variegated with white stripes. Mr. Hart's Rose has the white stripes more distinct: the flowers in these being less double than in several others, are frequently succeeded by fruit, and have ripe seeds, from which other varieties may be obtained. According to Parkinson, "sometimes one half of the petal is of a pale whitish colour, and the other half of a paler damask than common; or one petal is white or striped with white, and the other half bluish or striped with bluish; sometimes also all striped or spotted over, and at other times little or no stripes or marks, and the longer it remains blown open in the sun, the paler and the fewer stripes, marks or spots will be seen in it. The smell is of a sweet Damask Rose scent."

The Red Monthly Rose, the White Monthly Rose, which are so called from their continuing to blow in succession during the greater part of the summer; not that they blow in every month, as the name implies. They are in every respect like the Damask Rose; unless it be that they are more full of prickles than that.

The Blush Belgic Rose, which rises about three feet high, with prickly stalks: the leaves are composed of five or seven leaflets, which are oval, hairy on their under side, and slightly serrate: the peduncles and calyxes are hairy, and without prickles; the calyxes are large and semipinnate; the flowers very double, of a pale flesh colour, with little scent, generally in great quantities.

The Red Belgic Rose, which differs only in having the colour of the flower a deep red.

The Great Royal Rose, and the Imperial Blush Damask Rose.

The sixteenth species has slender stalks which trail upon the ground unless they are supported, and if trained up to a pole or the stem of a tree will rise twelve or fourteen feet high; they are armed with crooked reddish spines, and have

small leaves, with seven oval acute leaflets, of a lucid green, and serrate: the leaves continue on all the year: the flowers are small, single, white, and have a musky odour. In their natural place of growth they continue in succession great part of the year, but their time of flowering in this climate is June. It is a native of Germany.

The seventeenth has the branches with a great abundance of prickles, which fall off on the stems: the fruits are large and pear-shaped. It is a native of Austria and Italy.

The eighteenth species has the young shoots covered with a pale purplish bark, set with a number of small prickles like hairs: the older branches have but few thorns: the fruit is very large: the flower is thick and double as a red-rose, but so strong swelling in the bud, that many of them break before they can be full blown; and then they are of a pale red-rose colour, between a red and a damask, with a very thick broad hard umbone of short yellow threads in the middle: the segments of the calyx are quite entire: the smell is nearest a red rose.

The nineteenth has yellow hooked prickles on the stem, which is five or six feet high: the leaflets seven, very fragrant, elliptic or subovate, above smooth and wrinkled, underneath rust-coloured with resinous atoms or little dots: serratures glandular: the petioles also glandular and prickly: the peduncles muricate and in corymbs: the calyx glandular: the petals rose-coloured, white at the base: the fruit scarlet, muricate, but sometimes smooth, farinaceous, insipid.

The cultivated plant grows larger and more erect: the leaves are bigger and much sweeter than in the wild one, the rusty colour of them disappears, and the whole puts on a more vigorous appearance: the sweet scent is supposed to proceed from the gland. It is a native of most parts of Europe.

There are varieties with double flowers: as the Common Double Sweet Briar, the Mossy Double Sweet Briar, the Evergreen Double Sweet Briar, the Marbled Double Sweet Briar, the Red Double Sweet Briar, the Royal Sweet Briar, and the Yellow Sweet Briar.

The twentieth species, which is mostly denominated the Moss Rose, from the moss-like pubescence on the calyx, has the stalks and branches closely armed with brown spines: the peduncles and calyx are covered with long hair-like moss: the flowers are of an elegant crimson colour, and have a most agreeable odour. It is known to us only in its double state, and the country to which we are indebted for it is not ascertained.

The twenty-first, or Musk Rose, rises with

weak stalks to the height of ten or twelve feet, covered with a smooth greenish bark, and armed with short strong spines: the leaflets seven, light-green and serrate: the flowers in large bunches, in form of umbels, at the end of the branches, are white, and have a fine, musky odour, appearing in July and August, and continuing in succession till the frost stops them. The stalks are too weak to support themselves. There is a variety with double flowers.

The editor of Miller's Dictionary considers the Evergreen Musk Rose of Miller to be the same with this.

The twenty-second species is a low shrub, with reddish-brown stems, the lower half or thereabouts of which is covered with straight awl-shaped slender white not pungent prickles; the upper part is quite naked: the stipules ciliate-glandular at the edge: the petioles hispid, and glandular: the leaflets commonly seven, smooth on both sides, ovate, biserrate, ciliate, glandular: the peduncles naked, unarmed: flowers solitary, red, middle-sized. It is a native of the Alps, &c., flowering in June and July.

The twenty-third has a height seldom exceeding three feet: the flowers large in proportion to the plant, semidouble, with great richness of colour (dark red) uniting a most delightful fragrance, coming out in succession during the greater part of the year, only more sparingly in the winter months. The segments of the calyx leafy at the end, one larger than the rest: the germs and peduncles sometimes, but rarely, smooth. It is a native of China.

The twenty-fourth species in its wild state has ovate leaves, smooth and deep green above, paler and slightly hairy underneath, unequally serrate and blunt: the stem and petioles villose, prickly: the peduncles solitary, long, hispid: fruits ovate, smooth, but more frequently having a few slender prickles on them: calyxes smooth, green, half-pinnate. It is a native of Europe, China, &c.

According to Parkinson, there are two varieties of the White Garden Rose; one attaining sometimes the height of eight or ten feet, with a stock of a great bigness, the other seldom higher than a Damask Rose. Both have somewhat smaller and whiter-green leaves than in many other roses, five most usually on a stalk, and paler underneath; as also a whiter-green bark, armed with short prickles. The flowers in the one are whitish, with an eye of blush, especially towards the bottom, very double, and for the most part not opening so fully as the Red or Damask Rose. In the other more white, less double, and opening more. Some have only two or three rows of petals; and all have little or no smell.

Culture.—In all the sorts the increase may be effected by suckers, layers, or by budding upon stocks of other sorts of roses; but this last method is only practised for some peculiar sorts, which do not grow well upon their own stocks, and send forth suckers sparingly. Where more sorts than one are to be had upon the same plant, such sorts only should be budded upon the same stock as are nearly equal in their manner of growth, otherwise the strong one will draw all the nourishment from the weaker.

The suckers should be taken off in October, and planted out either in nursery-rows, or the places where they are to remain; as where they are permitted to stand upon the roots of the old plants more than one year, they grow woody, and do not form so good roots as if planted out the first year.

The best method to obtain good-rooted plants is to lay down the young branches in autumn, which will take good root by the autumn following; especially when watered in dry weather; when they may be taken off from the old plants, and be planted out where they are to remain. The seeds are sometimes sown in the autumn, to produce new varieties, in beds of light mellow earth, or in drills, especially for the Common Sweet Briar kinds, and for raising hedges of them.

Almost all the sorts delight in a rich moist soil and an open situation, in which they produce a greater quantity of flowers, and those much fairer, than when they are upon a dry soil, or in a shady situation. The pruning which they afterwards require is only to cut out their dead wood, and take off all the suckers, which should be done every autumn; and if there are any very luxuriant branches, which draw the nourishment from the other parts of the plant, they should be taken out, or shortened, to cause them to produce more branches, if there be occasion for them to supply a vacancy; but it is best to avoid crowding them with branches, which is as injurious to these plants as to fruit-trees; for, if the branches have not equal benefit from the sun and air, they will not produce their flowers so strong, or in so great plenty, as when they are more open, and better exposed to the sun, so as to have a more free circulation of air. As the Moss Provence Rose seldom sends out suckers, and does not strike very freely by layers, it is often increased by budding it upon stocks of the other sorts; but the plants are best when raised from layers.

The best sort for flowering early and late is the Monthly, next to which in flowering in the open air is the Cinnamon, which is immediately followed by the Damask Rose, then the Blush, York, and Lancaster; after which, the Provence,

Dutch Hundred-leaved, White, and most other sorts : and the latest sorts are the Virginia and Musk Roses, which, if planted in a shady situation, seldom flower until September ; and, if the autumn proves mild, continue often till the middle of October. And the plants of the two sorts of Musk Roses should be placed against a wall, pale, or other building, that their branches may be supported, otherwise they are so slender and weak as to trail upon the ground. These plants should not be pruned until spring, because their branches are somewhat tender ; so that when they are cut in winter, they often die after the knife ; these produce their flowers at the extremity of the same year's shoots in large bunches, so that their branches must not be shortened in the summer, lest the flowers should be cut off. The shrubs will grow to be ten or twelve feet high, and must not be checked in their growth, if intended to flower well. They are all highly ornamental plants, mostly for the shrubbery borders and clumps, being planted according to their habits of growth.

ROSMARINUS, a genus containing plants of the hardy shrubby evergreen kind.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Verticillatæ*.

The characters are : that the calyx is a one-leaved perianth, tubular, compressed above : mouth upright, two-lipped : upper lip entire, lower bifid : the corolla unequal : tube longer than the calyx ; border ringent : upper lip two-parted, upright, shorter, acute, with the edges bent back : lower lip bent back, trifid ; the middle segment very large, concave, narrow at the base ; the lateral ones narrow, acute : the stamina have two awl-shaped filaments, simple with a tooth, inclined towards and longer than the upper lip. Anthers simple : the pistillum is a four-cleft germ : style of the same figure, situation and length with the stamens : stigma simple, acute : there is no pericarpium : calyx containing the seeds at the bottom : the seeds four, ovate.

The species are : 1. *R. officinalis*, Official Rosemary.

It has a strong woody fibrous root. The stem shrubby, covered with a rough gray bark, divided into many branches, and in gardens

rising frequently to the height of eight or ten feet ; but in its natural state much lower. The leaves numerous, sessile, linear, entire, blunt, contracted at the edges, dark green above, grayish or whitish underneath, with small glandular excavations, placed in whorls on the branches : the flowers from the axils of the leaves, from six to twelve together, large, pale blue, sometimes white with blue spots and dots. It is a native of the South of Europe, &c., flowering from January to May.

There are varieties with narrow leaves ; with broad leaves ; with silver-striped leaves, and with gold-striped leaves.

Culture.—In all the sorts it may be effected by planting slips or cuttings in the early spring months as from March to May ; as well as by layers, in performing the first methods of which, a quantity of young shoots should be cut or stripped off from about five or six to eight or ten inches long, stripping off the lower leaves, and then planting them in a border of light earth, in rows a foot asunder, giving a good watering and repeating it frequently till they are rooted, which they effect in a short time, in the same year, shoot at top, and become tolerable little plants by autumn ; when about the beginning or middle of September, or in spring following, they may be transplanted where they are designed to remain for growth.

The layers should be laid down in any of the convenient lower young branches, into the earth, in the spring, summer, or autumn, and they will be well rooted by autumn following, when they may be taken off and planted out where they are to remain for plants.

Almost all the varieties are moderately hardy evergreen plants, though the common green sorts are the most so ; the striped kinds being liable to suffer by hard frosts, if much exposed, or planted in wet ground, of course they as well as all the sorts should have a warm situation and dry soil : some of the variegated kinds should also be potted, in order to have shelter of a green-house in winter. They are most durable in dry poor soils.

They afford variety in the border, clumps, and other parts of gardens and shrubberies.

ROYENA, a genus containing plants of the shrubby evergreen exotic kind for the green-house.

It belongs to the class and order *Decandria Digynia*, and ranks in the natural order of *Bicornes*.

The characters are. that the calyx is a one-leaved, pitcher-shaped, five-cleft, permanent perianth : the corolla one-petalled : tube the length of the calyx : border spreading, revolute, five-

parted; segments ovate: the stamina have ten very short filaments fastened to the corolla: anthers oblong, acute, twin, erect, the length of the tube: the pistillum is an ovate germ, ending in two styles, a little longer than the stamens: stigmas simple: the pericarpium is an ovate capsule, four-grooved, one-celled, four-valved: berry globular, fleshy, four-celled, covered by the permanent corolla: the seeds, four nuts, oblong, triangular, wrapped in an aril: seeds solitary, in all four or two, oblong or elliptic, subtriquetrous or plano-convex.

The species cultivated are: 1. *R. lucida*, Shining-leaved Royena, or African Bladder-nut; 2. *R. villosa*, Heart-leaved Royena, or African Bladder-nut; 3. *R. glabra*, Myrtle-leaved Royena, or African Bladder-nut; 4. *R. hirsuta*, Hairy-leaved Royena, or African Bladder-nut.

The first is in height eight or ten feet, putting out branches on every side: the leaves alternate, shining, continuing all the year: the flowers from the wings of the leaves along the branches, having little beauty: the fruit a berry covered with the permanent calyx, which is coriaceous, torn, and striated within, globular, smooth, red above, pale below, four-celled: the flesh or pulp firm, whitish, almost like that of the apple: the cells filled with a pulp clear like glass, and not invested with any proper membrane, two of them commonly abortive, compressed, crescent-shaped: the seeds solitary, and two or four in all. It is a native of the Cape, flowering in May and June.

The second species resembles the preceding; but the branches are villous: the leaves elliptic or oblong, cordate at the base, tomentose underneath, bluish on short villose petioles: the flowers axillary, nodding, solitary, on villose peduncles the length of the flowers: the bractes two, opposite, ovate acute, pubescent, larger than the calyx and immediately under it, deciduous.

The third rises with a shrubby stalk, five or six feet high, sending out many slender branches, covered with a purplish bark: leaves less than those of the Box-tree, entire, of a lucid green, and continuing all the year. The flowers come out from the wings of the leaves round the branches, and are white. Fruit roundish, purple, ripening in the winter. It flowers in September.

The fourth species rises with a strong woody stalk seven or eight feet high, covered with a gray bark, sending out many small branches alternately: the leaves about an inch long, and a quarter of an inch broad in the middle, covered with soft hairs: the flowers come out on short peduncles from the side of the branches; are of

a worn-out purple colour and small: they appear in July, but are not followed by seeds in this climate.

Culture.—These plants are often rather troublesome in raising, but their culture may be attempted by cuttings and layers. The cuttings should be made from the young shoots, and be planted in the early spring in small pots filled with a loamy earth, plunging them in a very moderate hot-bed, covering them carefully with hand glasses, refreshing them often with water in small proportions. When they have stricken roots and are begun to shoot, inure them gradually to the open air, and when they are well rooted remove them into separate small pots, managing them afterwards as other rather tender green-house plants, such as the Orange-tree, &c.

The layers may be made from the young bottom shoots, laying them carefully down by slitting them as for Carnations, watering them often in the warm season, but very moderately in the cold. When they are become well rooted, take them off and plant them in separate pots in the same manner as the cuttings, giving them the same sort of management afterwards.

The last sort often sends up suckers from the roots, and may sometimes be increased by planting in the same way as the cuttings.

They afford variety among other green-house plants.

RUBIA, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Tetrandria Monogynia*, and ranks in the natural order of *Stellata*.

The characters are: that the calyx is a very small perianth, four-toothed, superior: the corolla one-petalled, bell-shaped, four-parted, without a tube: the stamina have four awl-shaped filaments, shorter than the corolla: anthers simple: the pistillum is a twin inferior germ: style filiform, bifid at top: stigmas capitate: the pericarpium-berries two, united, smooth: the seeds solitary, roundish, umbilicate.

The species mostly cultivated is *R. tinctorum*, Dyer's Madder.

It has a perennial root, and an annual stalk. The root is composed of many long, thick, succulent fibres, almost as large as a man's little finger; these are joined at the top in a head, like the roots of Asparagus, and strike very deep into the ground, being sometimes more than three feet in length. From the upper part (or head of the root) come out many side roots, which extend just under the surface of the ground to a great distance, whereby it propagates very fast; for these send up a great number of

shoots, which, if carefully taken off in the spring, soon after they are above ground, become so many plants. These roots are of a dark colour on their outside, somewhat transparent, and have a yellowish red pith in the middle, which is tough, and of a bitterish taste; from the root arise many large, four-cornered, jointed stalks, which in good land will grow five or six feet long, and, if supported, sometimes seven or eight; they are armed with short herbaceous prickles, and at each joint are placed five or six spear-shaped leaves, about three inches long, and near one broad in the middle, drawing to a point at each end; their upper surfaces are smooth, but their midribs on the under side are armed with rough herbaceous spines; the leaves sit close to the branches in whorls. From the joints of the stalk come out the branches, which sustain the flowers; they are placed by pairs opposite, each pair crossing the other; these have a few small leaves toward the bottom, which are by threes, and upward by pairs opposite; the branches are terminated by loose branching spikes of yellow flowers, which are cut into four segments resembling stars. They appear in June. It is a native of the South of Europe, the Levant, and Africa.

Madder is so essential to dyers and calico-printers, that these businesses cannot be carried on without it.

Culture.—They are increased by offsets or suckers, from the roots of the old plants in the spring, as April or the following month; which should be slipped off soon after they appear above ground, by opening the earth round the roots, and taking off the side suckers with as much root-part and fibres to each as possible, preserving the tops entire; which should be planted directly, in the manner directed below. The ground being well prepared by frequent deep ploughing, or trenching over, and the proper quantity of sets or suckers provided, they should with a dibble be planted in rows two feet asunder, and one distant in the row, putting each plant low enough in proportion to the length of its root, leaving most of the green top out of the ground, and closing the earth well about each set, as the work proceeds. Some set these plants in beds, three rows length-ways; at two feet distance, with wide alleys between bed and bed, in order for landing up the crowns of the roots two or three inches deep in winter.

They shoot up into stalks the same year in either mode, but the roots require two or three years' growth before they are large enough for use; during which period they should be kept clean from weeds all the summer by broad-hoeing, in dry weather; and in autumn, when the

stalks decay, cutting them down, and then slightly digging the ground between the rows, raising it somewhat ridge-ways along the rows of the plants, an inch or two thick over their crowns; or, if they are in beds, they may be landed up from the alleys to the same depth; the same culture being repeated till the autumn of the third year, when the roots will be fit for taking up for use. This is performed by trenching the ground the way of the rows, beginning at one end of it, and opening a two-feet-wide trench close along by the first row of plants, digging down to the depth of the roots to get them clean out to the bottom; then opening another trench close to the next row, turning the earth into the first; and so on, trench and trench, till the whole is taken up and removed.

These plants succeed best in a light rich deep soil: the roots are sometimes used fresh for dyeing, being prepared by washing and pounding; but commonly when designed for keeping, or to be sent to a distance, are dried in some covered airy shed; then all the mould being rubbed off, and the roots made sufficiently dry, are sold to those who manufacture them for use, if not performed by the cultivator: this consists in drying them in a kiln or some stove-house, &c. then thrashing them to beat off the outer skin, in order to separate it from the inner part of the root, as being of an inferior quality. The roots being then dried in a kiln about twenty-four hours, are removed to a mill or pounding-house, where they are pounded in a long hollow oaken block, with stampers kept in motion by the mill; and when thus reduced to powder, sifted and put up in casks.

The plants are sometimes employed for variety in the border or other open parts of gardens or pleasure-grounds.

RUBUS, a genus containing plants of the under-shrubby and herbaceous perennial kind.

It belongs to the class and order *Icosandria Polygynia*, and ranks in the natural order of *Senticosæ*.

The characters are: that the calyx is a one-leaved, five-cleft, perianth: segments oblong, spreading, permanent: the corolla has five roundish petals, the length of the calyx, from upright spreading: the stamina have numerous filaments, shorter than the corolla, inserted into the calyx: anthers roundish, compressed: the pistillum has numerous germs: styles small, capillary, springing from the side of the germ: stigmas simple, permanent: the pericarpium is a berry compounded of roundish *acini*, collected into a convex head, concave below; each one-celled: the seeds solitary, oblong: the receptacle of the pericarps conical.

The species are: 1. *R. idæus*, Raspberry; 2. *R. occidentalis*, Virginian Raspberry; 3. *R. odoratus*, Flowering Raspberry; 4. *R. fruticosus*, Common Bramble; 5. *R. hispidus*, Bristly Bramble; 6. *R. cæsius*, Dewberry Bramble; 7. *R. arcticus*, Dwarf Crimson Bramble; 8. *R. Chamæmorus*, Mountain Bramble, or Cloud-berry.

The first has the stems suffruticose, biennial, upright, round, aculeate-hispid, or thick set with small prickles, two feet high; they produce fruit the second year, after which they lie down. The leaflets rhomb-ovate, acute, marked with lines, unequally serrate, white underneath. The petioles pubescent, prickly. The peduncles hispid. The flowers in panicles. The fruit red, grateful to the smell and taste, deciduous, bristly with the permanent styles placed upon a conical receptacle. It is a native of many parts of Europe, flowering in May and June.

The varieties are: the Red-fruited, the White-fruited, the Twice-bearing, of which the first crop ripens in July, and the second in October, those of the latter season having seldom much flavour; the Smooth Raspberry, and the large Antwerp. The sorts mostly cultivated, according to Mr. Forsyth, are: the Early White, the Double-bearing White, the Large Common White, the Large Red, the Large Red Antwerp, the Large White Antwerp, the Smooth Cane Double-bearing, and the Woodward's New Raspberry.

The second species rises with purplish stalks, a little higher than the common sort. The leaves are of a lucid green on their upper side, but hoary on their under; their foot-stalks are taper; the fruit is of a deep black when ripe, has little flavour, and ripens late in autumn. It is a native of North America, flowering in May and June. It varies with a red fruit, more acid and pleasant than the European Raspberry.

The third has a perennial creeping root. The stems many, from four to seven feet high, about the size of a man's little finger, covered with a smooth bark of a light brown colour, and branching out a little towards the top. The leaves six inches long and seven inches broad, cut into three, four, or five angular lobes, ending in acute points, serrate, having several veins arising from the midrib, running upwards, diverging towards the borders, deep green above, but light green and smooth beneath; on foot-stalks four inches long, coming out alternately. The flowers in loose terminating bunches, each on a long peduncle. Petals large, roundish, of a light purple colour. The fruit is rarely produced here; but in North America, its native country, it is like the common Raspberry, only

not so pleasant. It flowers from June to September.

The fourth species has very long, trailing, or rather arching, woody stems, of a purplish hue; tough, with the angles strongly marked, and the prickles hooked. The leaves quinate, or sometimes ternate; leaflets somewhat elliptical, doubly-serrate, acute, dark-green and shining above, white and downy beneath; but sometimes the under side is merely hairy and of a paler green. All the leaflets are petioled; and the petioles are prickly. The stipules bristle-shaped. The panicles many-flowered, subracemed, tomentose. The fruit of a dark violet colour, with a mawkish sweet taste, composed of very numerous acini or grains. There are several varieties; but that which is chiefly introduced as a garden shrub is the Double-flowered Bramble.

The fifth has the stems with long procumbent woody shoots like those of the vine; these together with the petioles have stiff bristles scattered over them. The leaflets gash-serrate, the middle one petioled. The peduncles also are hispid. It is a native of Canada, flowering in August.

The sixth species has the stems prostrate, round, rooting, pale green with a vivid glaucous tinge: though woody, they are only annual, or at most biennial. The leaflets gashed and serrate, downy (not hoary) beneath: the lateral leaflets sessile, generally lobed on the outside, of various forms. Stipules lanceolate. The petioles downy, prickly, obscurely channelled above. The flowers few together, in terminating, downy, somewhat prickly panicles. The fruit black, with a bright blue tinge or bloom, composed of few large grains. Its flavour is agreeably acid, without the faint taste of the fourth sort. It is a native of Europe, flowering in June and July.

The seventh has a creeping root, but no runners. The stems are from a hand to a span in height, upright, simple, angular. The leaves unequally serrate, commonly altogether smooth. The flowers solitary, peduncled, terminating, deep rose-coloured, with the petals sometimes jagged. The fruit purple, sweet and fragrant, very pleasant, and, according to Linnæus, almost as large as a mulberry. It is a native of the North of Europe.

The eighth species is a plant of an elegant appearance, with a creeping root, a simple stem, hardly a foot high, upright; mallow-like, but smooth and hardish leaves, petioled, cordate, five-lobed, plaited, wrinkled, unequally serrate. The flowers terminal, peduncled, white; male and female, the former with short abortive pistils, the latter with abortive stamens. The berries are of a tawny or dull orange colour, com-

posed of many acini, acid, mucilaginous and not unpleasant. It is a native of Sweden, &c.

Culture.—In the first sort and varieties it may be effected by suckers and layers. The plants should always have a portion of ground to themselves, being planted at the distance of about six feet from row to row, and four in the rows, with the exception of the Early White sort, which may be set out closer.

According to Mr. Forsyth, the ground should first be well trenched over and dunged; then, making choice of the strongest and finest plants that come out from the sides of the stools, where they have been standing for some years, or encouraging the strongest plants that come out betwixt the rows after digging, which should be done annually, they may be planted out as above. In digging the ground, it frequently happens that the roots are cut with the spade, which occasions a great number of small plants to come up; of these the strongest and finest should, he says, be selected, heeling up all the superfluous ones. But he prefers laying down some of the strongest outside shoots in the month of March; as by the following autumn they will make fine roots, and may be planted out in a quarter or piece of ground where they are intended to remain. These will not be so liable, he thinks, to throw out suckers as those which are produced from suckers. The fresh pieces of ground should always be planted in moist weather, as the roots are very delicate, and liable to be hurt when exposed to a dry air. If, however, they are planted in dry weather, he advises that care be taken to moisten the roots with water, and cover them well with wet litter, or leaves, during the time in which they are planting out. In performing the work a trench should be opened with a spade along the line where the suckers or layers are to be planted, cutting off all the small fibry roots with a knife, leaving only the stronger roots; putting them into the trench, and covering them with some earth; then watering them well, and throwing the remainder of the earth over them, letting them remain till you have finished planting the piece; then, where you first began to plant, beginning to tread the ground with the foot as hard as possible along each of the trenches, and in the same direction as planted; then with a spade levelling all the ground smooth, and running it over with a rake, taking off any stones and rubbish that may be left on the surface, so as to render it perfectly even.

The plants should be watered two or three times a week when the season is dry till they have taken root; and it will be necessary to stake the Antwerp, and other strong-growing sorts, with stout stakes, running a couple of small rails

at top to tie the branches to, which will prevent their being broken by the wind, or beaten down by the rain. The Early White and smaller sorts may be plaited together at top, tying them round with the small yellow willow, which will keep them together. Some of the Early Raspberries may, he says, be planted between the trees on a west aspect, to produce early fruit before those in the quarters come in. The Antwerps thrive exceedingly well against north walls or palings, and produces late crops. Such as are planted against walls or palings should be tacked to them, to keep them in their places.

It is advised that where any of the small red and white sorts are found they should be destroyed, planting the Large Red, the Smooth Cane Double-bearing, the Large Red and White Antwerps, the Large common White, the Double-bearing White, and Woodward's New Raspberry in their stead. In respect to the cutting or pruning of these plants, some, Mr. Forsyth says, prefer pruning them in autumn, a practice of which he by no means approves of. As they bear the fruit on the wood of the preceding year, they are, he thinks, very liable to be killed by the frost in severe winters; but, by deferring the pruning till the month of February, there will be a great choice of fine wood for bearing the following summer, being careful to root out or cut down all the wood that bore fruit the preceding year, which generally dies, selecting only from five to seven of the most vigorous and strong shoots from the last year's wood to bear fruit the ensuing season. These shoots may, he says, be pruned to the length of three or four feet, according to their strength, when they are of the Smooth Cane Double-bearing sort (which generally bears a second crop in autumn, and will in fine seasons continue bearing from June to November); but, if the Large Antwerp, the shoots should be left five or six feet long in these prunings.

In regard to the Early White, which never grows so strong as the above sorts, it should, he says, be shortened to two feet and a half, or three feet. These should be planted in rows about three feet distant from each other, and two feet from plant to plant in the rows; always remembering to keep them clear of suckers, and to cut out the dead or last year's wood, as above; making choice of the strongest shoots for bearing wood. Great care should, however, be taken not to cut off the little spurs on the sides, which bear the fruit in this kind.

Plants of this sort continue in bearing five or six years; by which time a fresh plantation should be in readiness to succeed them. The young plants often bear some fruit the first year,

Rosa lutea
2 Single yellow Rose.

and come into full bearing in the second after planting. If they be suffered to remain more than five or six years on the same ground, he says, they degenerate and bear small fruit. And much care should be taken not to leave above eight or ten of the strongest shoots, rubbing off or pulling up all the superfluous ones; and keeping the ground well hoed and cleared of weeds between the rows, as well as in other places.

In the other sorts the increase may be effected by suckers, layers, cuttings, and dividing the roots, and in the two last or herbaceous kinds by seed.

The suckers should be taken up in autumn, winter, or spring, with roots; and the strongest be planted at once into the shrubbery, and the others in nursery-rows for a year or two, or till wanted for planting.

The layers should be made from the shoots, which may be done almost any time, as they readily emit roots at every joint, and become fit to plant out in the autumn following.

The cuttings should be taken off from some of the younger shoots, and divided into lengths a foot long, and planted in a shady border, either in the spring or summer season.

The roots in any of the raspberry or herbaceous sorts, when increased into large bunches, may be divided or slipped into several distinct sets, and planted out separately.

The last two sorts may likewise be raised from seeds, which should be taken from the ripened fruit, and sown in a moist situation where the plants are to remain, keeping the young plants clean afterwards.

The first species and varieties are highly useful for their fruit; for the table, preserving, and other culinary purposes.

The other sorts afford variety in the borders, clumps, and other parts of pleasure-grounds, among other hardy plants.

RUDBECKIA, a genus containing plants of the herbaceous biennial and perennial kinds.

It belongs to the class and order *Syngenesia Polygamia Frustranea*, and ranks in the natural order of *Compositae Oppositifoliae*.

The characters are: that the calyx is common with a double row of scales: scales flat, widish, curtailed, six in each row: the corolla compound radiate: corollets hermaphrodite, numerous, in a conical disk; females about twelve, very long in the ray: proper of the hermaphrodite, tubular-funnel-form, with a five-toothed border: female ligulate, lanceolate, with two or three teeth, flat, pendulous: the stamina in the hermaphrodites: filaments five, capillary, very short: anther cylindrical, tubular: the pistillum in the hermaphrodites: germ four-cornered: style filiform,

the length of the corollet: stigma two-parted, revolute: in the females: germ very small: style none: stigma none: there is no pericarpium: calyx unchanged: the seeds in the hermaphrodites solitary, oblong, crowned with a membranaceous four-toothed rim: in the females none: the receptacle chaffy, conical, longer than the common calyx: chaffs the length of the seeds, erect, channelled-concave, deciduous.

The species cultivated are: 1. *R. laciniata*, Broad Jagged-leaved Rudbeckia; 2. *R. digitata*, Narrow Jagged-leaved Rudbeckia; 3. *R. hirta*, Hairy Rudbeckia; 4. *R. purpurea*, Purple Rudbeckia; 5. *R. angustifolia*, Narrow Simple-leaved Rudbeckia; 6. *R. triloba*, Three-lobed Rudbeckia.

The first is by some divided into two species, which are thus described: the root of the former is perennial, but the stalk is annual: the lower leaves are composed of five broad lobes, deeply cut into acute points, and some of them jagged almost to the midrib; the outer lobe is frequently cut into three deep segments: the stalks rise seven or eight feet high, and divide at top into several branches; are smooth, green, and have single, oval heart-shaped leaves, some indented on their edges, others entire: the peduncles naked, terminated by a single flower with yellow rays, like the sun-flower, but smaller: the latter is also perennial, and has smooth green stalks; but they rise higher: the leaves have all five lobes, which are much narrower, end with sharper points, and are very acutely indented on their sides: the flowers are smaller, and the petals narrower. They are both natives of North America, flowering here in July.

The second species has a perennial root like the former: the leaves at bottom are composed of seven or nine lobes, some entire, others jagged to the midrib; they are of a dark green and smooth: the stalks rise six feet high, and divide into many branches; they are of a purple or iron colour, and very smooth: the stem-leaves towards the bottom are hand-shaped, and composed of five lobes; higher up they have but three lobes, and at top the leaves are single: the flowers are smaller than those of the preceding, but of the same shape and colour. It is a native of North America, flowering in August and September.

In the third, the root continues four or five years: the leaves are oblong, ovate, and hairy: the stalks rise a foot and half high, and have one or two leaves near the bottom: the peduncle is naked near a foot in length, and is terminated by one pretty large yellow flower, shaped like the sun-flower: the florets of the ray are very

stiff, and slightly indented at their points: the disk is very prominent, and of a dark purple colour. The flowers will continue six weeks, and there is a succession of them from the middle of July, till the frost puts a stop to them. It is a native of Virginia.

The fourth species is a perennial plant like the third. The leaves are longer and broader, are smooth, and have three veins: the peduncles are taller, and have two or three narrow leaves on each, placed alternately: on the top is one flower, with long narrow, reflexed, peach-coloured florets in the ray: the disk is very prominent, and of a dark purple colour: it flowers at the same time with the third, but the flowers are of not so long duration. It is a native of Carolina and Virginia.

The fifth has the root perennial: the stalks four or five feet high: the leaves narrow, smooth, opposite: the florets in the ray of the flower yellow, long, twelve in number: disk dark red: the scales of the calyx spreading and almost awl-shaped. It is a native of Virginia, flowering in August and September.

The sixth species is biennial: the lower leaves are divided into three lobes, but those upon the stalks are undivided: they are hairy, and shaped like those of the first sort: the stalks branch out on their sides, and are better furnished with leaves than the others: the flowers are very like those of the first sort, but smaller. It grows naturally in several parts of North America.

Culture.—All the sorts of these plants may be increased by offsets, parting the roots and seeds.

The offsets in the perennial sorts should be taken off and planted out in the early autumn: when the stems decay the roots may also be divided and planted out at the same time, or in the early spring months.

As these plants are often liable to go off soon, some should be frequently raised to keep up the stock; and as others have a tendency to become biennial, and decay without increasing the root, they should have the flower-stems cut down in the early summer, to encourage the growth of the root offsets, for slipping in the following autumn.

All the sorts may be raised from seed, and the biennial sorts must always be raised annually in that way; likewise such of the perennial kind as are biennially inclined, sowing the seeds in April, in a border of light earth, raking them in; and when the plants are two or three inches high, pricking them out in nursery-rows till autumn, then planting them out where they are to remain. They should have a light dry soil and rather warm situation.

They afford much ornament and variety in

the borders and clumps, among other flowering plants.

RUE. See RUTA.

RUMEX, a genus containing plants of the herbaceous perennial and woody evergreen kinds.

It belongs to the class and order *Hexandria Trigynia*, and ranks in the natural order of *Holoracea*.

The characters are: that the calyx is a three-leaved perianth: leaflets obtuse, reflex, permanent: the corolla has three ovate petals, bigger than the calyx, and like it, converging, permanent: the stamina have six capillary filaments, very short: anthers erect, twin: the pistillum is a turbinate-three-sided germ: styles three, capillary, reflexed, standing out between the clefts of the converging petals: stigmas large, lacinate: there is no pericarpium: corolla converging, three-sided, inclosing the seed: the seed single, three-sided.

The species cultivated are: 1. *R. acetosa*, Common Sorrel; 2. *R. scutatus*, French Sorrel; 3. *R. Patientia*, Patience Dock, or Rhubarb; 4. *R. sanguineus*, Bloody-veined Dock, or Bloodwort; 5. *R. Lunaria*, Tree Sorrel.

The first has a perennial root, running deep into the earth: the stem mostly simple, erect, round, deeply striated, leafy, from one to two feet high: the radical and lower stem-leaves on long foot-stalks, with a membranous cylindrical sheathing stipule embracing the stem and torn at the top; these leaves are arrow-shaped, blunt, entire or but little waved in their sides, but at the base cut into two or three large sharpish teeth pointing backwards, and not, as in some of the species, divaricated into a right angle with the outline of the leaf: the upper leaves sessile, gradually more entire, embracing, acute, a little rolled back; those at the top of the stem only slightly crisped at their base: a compound sort of whorled spike or branched panicle terminates the stem; its branches alternate and nearly erect: the barren flowers are on a separate plant from the fertile ones.

The whole herb is acid, with a degree of astringency, not unpleasant or unwholesome. It is often cultivated as a culinary herb.

There is a variety with broad leaves, termed Great Mountain Sorrel.

The second species has a hard, fibrous, perennial root: the stem from a foot to eighteen inches in height, very slightly angular, glaucous, smooth, dividing into alternate spreading branches: the leaves are cordate or hastate, glaucous, smooth, soft, fleshy, blunt, entire, an inch and half in length and breadth, on petioles two or three inches long, channelled within: the flowers in a sort of whorls, forming all together

• spike-shaped racemes, nodding and coming out three or four together on capillary pedicels from a white sheathlet: valves subcordate, large, bright rose-colour, entire, without any grains. It is a native of Germany, &c.

This, which is called Round-leaved Sorrel, is a more grateful acid than the first sort, and of course preferred for kitchen use, in soups, &c.

The third has a large root, dividing into many thick fibres, which run downwards; the bark is brown, but the inside is yellow, with some reddish veins: the leaves are broad, long, acute-pointed, on petioles of a reddish colour: the stems from four to six feet high, dividing towards the top into several erect branches, having a few narrow leaves on them, and terminated by spikes of large flowers, which appear in June. It is a native of Italy.

The fourth species has a fusiform root: the stem is upright, branched, angular, leafy, smooth; all the leaves petioled, smooth, veined, somewhat curled about the edge: the root-leaves very large, cordate at the base: racemes terminating, spreading, almost leafless; with the flowers in alternate bundles, pedicelled, nodding.

The fifth species rises with a woody stalk ten or twelve feet high, covered with a smooth brown bark, and sending out many branches: the leaves are smooth, roundish-heart-shaped, two inches long, and an inch and half broad, alternate upon pretty long footstalks: the flowers come out in loose panicles towards the end of the branches: are of an herbaceous colour, and sometimes succeeded by triangular seeds with smooth covers; but the seeds rarely ripen in this climate. It is a native of the Canary Islands.

Culture.—The first and second sorts and varieties may be increased by seed and parting the roots, but more particularly the first, as the latter may be very readily increased by the roots. The seeds should be sown in a bed or border in the early spring, as March, raking it in evenly. When the plants come up they should be regularly thinned, and when of some growth, in the summer, be planted out in rows on a bed or border, about eight or nine inches apart in the common sort, and in the other a foot or more, watering them well; when they will be proper to cut the latter end of the same summer and in the autumn, continuing for several years; but as the seedling plants in the first kind mostly produce larger leaves than the older plants, fresh supplies should be raised annually or every other year.

The parted roots may be planted out in the

same season, or in autumn, in rows a foot apart, giving them a good watering; when they grow readily, and furnish leaves in the latter end of summer and in the autumn.

The second sort is readily raised in this way. They afterwards only require to be kept clean, and to have the seed stems cut down in the summer, as well as the rank leaves in the autumn, that more full supplies of fresh leaves may be afforded.

The third and fourth sorts may be raised also from seeds in the same way, and the former from offsets of the root planted out in the autumnal season; when they grow very readily.

The last sort is easily increased by cuttings of the young shoots in the spring and summer months, being planted in pots at the former season, plunging them in a hot-bed; but in the latter they succeed without artificial heat, either in pots or the natural ground, being occasionally shaded and watered; when they become well rooted by the autumn.

The third and fourth sorts afford variety in the clumps and borders, and the last among the green-house collections.

RUSCUS, a genus containing plants of the shrubby and under-shrubby evergreen kind.

It belongs to the class and order *Dioecia Syngenesia*, and ranks in the natural order of *Sarmentaceæ*.

The characters are: that in the male, the calyx is a six-leaved perianth, from erect-spreading; leaflets ovate, convex, with the lateral margin reflexed: the corolla has no petals, unless the alternate calyx-leaves be called so: nectary central, ovate, the size of the calyx, inflated, erect, coloured, perforated at the top: the stamina have no filaments: anthers three, spreading, placed on the top of the nectary itself, united at the base—female: the calyx is a perianth as in the male: the corolla petals as in the male: nectary as in the male: the pistillum is an oblong-ovate germ, concealed within the nectary: style cylindric, the length of the nectary: stigma obtuse, prominent beyond the mouth of the nectary: the pericarpium is a globular, three-celled berry: the seeds two, globular.

The species cultivated are: 1. *R. aculeatus*, Prickly Butcher's Broom; 2. *R. Hypophyllum*, Broad-leaved Butcher's Broom; 3. *R. Hypoglossum*, Double-leaved Butcher's Broom; 4. *R. racemosus*, Alexandrian Laurel; 5. *R. androgynus*, Climbing Butcher's Broom.

The first has the roots thick, white, twining about each other, putting out frequent fibres like those of the asparagus, oblique, striking deep in the ground: the stem suffruticose, tough, stiff,

green, round, striated, from eighteen inches to three feet in height, sending out from the sides many short branches; having many leaves on them, nearly of the same shape and size with those of myrtle, but very stiff, and ending in sharp prickly points: they are alternate, about half an inch long, and one-third of an inch broad near the base, ovate, quite entire, sessile: from the middle of the leaf above comes out a single flower, on a very short pedicel; it is small, and yellowish green or purplish; when it first appears, it is the size and shape of a small pin's head; when expanded, composed of three outer widish calyx-leaves, and three inner narrower like rays, ending in a narrow point. The female flowers are succeeded by berries, which are red, bigger than those of the asparagus, and almost as large as some cherries, of a sweetish taste; having two large orange-coloured seeds in each: the flowers come out in March and April. It is a native of the Southern parts of Europe.

The second species has the roots with large knotty heads, and long thick fibres like those of the preceding sort; from which arise many tough limber stalks near two feet high: the leaves stiff, ovate-oblong, ending in points, more than two inches long and almost one broad, placed alternately: the flowers are produced on the under surface of the leaves near the middle, sitting close to the midrib; are small and herbaceous: the female flowers are succeeded by small red berries about the size of those of juniper. It is a native of Italy, flowering in May.

The third has the root like the preceding: the stems about ten inches high: the leaves lanceolate, about three inches long, and one inch broad in the middle, drawing to a point at both ends, and having several longitudinal veins running from the footstalk to the point: they are mostly alternate, but sometimes opposite: on the middle of the upper surface comes forth a small leaf of the same shape; and at the same point, from the bosom of the small leaves, come out the flowers, which are of a pale yellow colour. The berries are almost as large as those of the first sort; are red, and ripen in winter. It is a native of Italy, &c. flowering in April and May.

The fourth species has roots like those of the other species: the stalks slender and much more pliable: they rise about four feet high, and send out many side branches: the leaves oblong, acute-pointed, about two inches long, and one-third of an inch broad, rounded at the base, smooth, of a lucid green, placed alternately, and sessile: the flowers are in long bunches at the end of the branches, of an herbaceous yellow colour: the berries like those of the first sort,

but smaller, ripening in winter. It is a native of Portugal.

The fifth species sends out pliant stalks which rise seven or eight feet high, and have several short branches proceeding from their sides: the leaves are stiff, about two inches long, and one inch broad towards their base, where they are rounded to the footstalk, but they end in acute points; many longitudinal veins run from the footstalk to the point: the flowers are produced in clusters on the edges of the leaves, and are white: the berries yellowish red, not so large as those of the first sort. It differs from the other sorts in having androgynous flowers divided into six equal segments to the bottom, but falling off in one piece, and arising from the edge, and not the disk of the leaf. It is a native of the Canary Islands, flowering most part of the summer.

Culture.—They are capable of being readily increased by the roots, which send up numerous stalks or suckers which may be taken up in autumn, winter, or spring in open weather, and divided into many separate sets each forming a proper plant, though they need not be divided very small unless where a great increase is required, planting the largest at once where they are to remain, and the smallest in nursery-rows, &c., when each plant soon increases by offsets, and assumes a bushy growth.

They are capable of being raised from seeds, but they often remain in the ground till the second spring. The seeds of the hardy sorts should be sown in any bed or border an inch deep, and the tender kind in pots, placed under shelter in cold weather; and when the plants are a year old, pricking them out in March, the hardy sorts in nursery-beds for two or three years, and the tender sorts in pots.

The different hardy sorts are proper for the verges of shrubberies, or any close plantations, as they thrive under the drip of trees, and remain green the year round.

But the last tender sort requires the shelter of a green-house in winter, where it affords variety among other potted plants.

RUSH, FLOWERING. See BUTOMUS.

RUSH, SWEET. See ACORUS.

UTA, a genus containing plants of the under-shrubby evergreen kind.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Multisiliquæ*.

The characters are: that the calyx is a five-parted perianth, short, permanent: the corolla has five petals, spreading subovate, concave; with narrow claws: the stamina have ten filaments, awl-shaped, spreading, the length of the

R U T

corolla, widish at the base: anthers erect, very short: the pistillum is a gibbous germ, inscribed with a cross, surrounded at the base by ten honey-dots, raised on a receptacle punctured with ten honey-pores: style erect, awl-shaped: stigma simple: the pericarpium is a gibbous capsule, five-lobed, half-five-cleft, five-celled, opening into five parts between the tips: the seeds very many, rugged reniform-angular.

The species cultivated are: 1. *R. graveolens*, Common Rue; 2. *R. montana*, Mountain Rue; 3. *R. chalepensis*, African Rue; 4. *R. patauna*, Three-leaved Rue.

The first has the root woody, branched: the stems frutescent, covered with a rugged, gray, striated bark, eighteen inches high and more: the branches, especially the young ones, smooth and pale green: the leaves glaucous, pulpy, dotted, divided like the umbellate plants, doubly pinnate, or more properly superdecompound: the leaflets obovate, sessile; the lower ones smallest; the end one commonly trifid, with the middle lobe much larger than the rest: the flowers in a branching corymb on subdivided peduncles. It is a native of the South of Europe; flowering from June to September.

The varieties are: the Common Broad-leaved Rue, the Narrow-leaved Rue, and the Variegated-leaved Rue.

The second species has the lower leaves composed of several parts, which are joined to the midrib in the same manner as other branching winged leaves, and have linear leaflets standing without order: the stalks are from two to three feet high, branching out from the bottom, and garnished with leaves divided into five parts, and those at the top into three, which are as small and narrow as the bottom leaves; are of a gray colour, but not so feid as those of the preceding: the flowers grow at the end of the branches in loose spikes, which are generally reflexed. It is a native of the South of Europe, and Barbary, flowering in August and September.

The third is very like the first, and is its off-

R U T

spring: the first flowers are five-cleft, and the others four-cleft, as in that: the stem is three feet high, upright, round, very much branched: the leaves superdecompound, oblong-ovate, smallish, cinereous, smooth, strong-smelling: the flowers in a terminating panicle. It is a native of Africa.

There are varieties with broad leaves and with narrow leaves.

In the fourth species the stalk rises singly from the root, is about a foot high, and herbaceous: the leaves alternate, narrow: the stalk branches at the top in form of an umbel, sustaining many yellow flowers, composed of five entire plane petals, having no hairs on their borders: it seems to be a plant of short duration. It was found in Italy.

Culture.—All the species and varieties may be readily increased by seed, slips, and cuttings. The seed should be sown in the open ground, in March or April, on a bed of light earth, raking it in: the plants soon come up, which when two or three inches high should be planted out in nursery-rows, and watered till fresh rooted. And from the scattered or self-sown seeds of the common sort, many young plants often rise in autumn and spring, which form good plants; but by slips or cuttings is the most expeditious method of raising all the sorts, as every slip or cutting of the young wood will readily grow. It is the only method by which the different varieties can be continued distinct. The slips or cuttings should be made from the young shoots six or eight inches long, and planted in a shady border, in rows half a foot asunder, giving a good watering, and repeating it occasionally; by which they will soon emit roots below and shoots at top, so as to form little bushy plants by the autumn following.

They all afford variety in the borders and other parts, and the first sort and varieties are useful medicinal plants. The third sort should have a dry soil and sheltered situation.

SACCHARUM, a genus containing a plant of the tender perennial reed kind.

It belongs to the class and order *Triandria Digynia*, and ranks in the natural order of *Gramina*.

VOL. II.

S A C

The characters are: that the calyx is a two-valved glume, one-flowered: valves oblong-lanceolate, acuminate, erect, concave, equal, awnless, surrounded with a long lanugo at the base: the corolla two-valved, shorter, sharpish, very tender: nectary two-leaved, very small: the sta-

s B

mina have three capillary filaments, the length of the corolla: anthers somewhat oblong: the pistillum is an oblong germ: styles two, feathered: stigmas plumose: there is no pericarpium: corolla invests the seed: the seed single, oblong.

The species cultivated is *S. officinarum*, Common Sugar-cane.

It has a jointed root, like that of other sorts of cane or reed: from this arise four, five, or more shoots, proportionable to the age or strength of the root, eight or ten feet high, according to the goodness of the ground: in some moist rich soils, canes have been measured near twenty feet long; but these are not near so good as those of middling growth; abounding in juice, but having little of the essential salt: the canes are jointed, and these joints are more or less distant, in proportion to the soil: a leaf is placed at each joint, and the base of it embraces the stalk to the next joint above its insertion, before it expands; hence to the point it is three or four feet in length, according to the vigour of the plant; there is a deep whitish furrow or hollowed midrib, which is broad and prominent, on the under side; the edges are thin, and armed with small sharp teeth, which are scarcely to be discerned by the naked eye, but will cut the skin of a tender hand, if it be drawn along it: the flowers are produced in panicles at the top of the stalks; are from two to three feet long, and composed of many spikes nine or ten inches in length, which are again subdivided into smaller spikes: these have long down inclosing the flowers, so as to hide them from sight: the seed is oblong-pointed, and ripens in the valves of the flower. It is a native of both the Indies, and the Islands of the South Seas.

There are three remarkable varieties mentioned by Loureiro, differing in the culm, not in the flower: the White Sugar-cane, with the culm long, white, of a middling size, very sweet, the knots distant; the Red Sugar-cane, with the culm short, thicker, red, very juicy, the knots approximate; the Elephantine Sugar-cane, with the culm very thick, red, long, less sweet, the knots approximate: and there are, probably, no others in a plant so much cultivated.

Culture.—This plant is capable of being increased by slips or suckers from the root, and by cuttings of the main stalks; but here generally by slips from the bottom; or any side-shoots arising from the stems near the root, having earth raised about the bottom part will soon emit fibres, and be fit for separation: the slips or offsets may be taken off at any season in which they appear fit for the purpose, being

careful to detach them with some fibres to each, and plant them separately in pots of rich earth, plunging them in the bark-bed, watering and occasionally shading them till they have got root, retaining them always in the bark-bed in the stove, treating them as other exotics of that sort.

They afford variety among other stove plants.

SALIX, a genus containing plants of the deciduous tree aquatic kind.

It belongs to the class and order *Dioecia Diandria*, and ranks in the natural order of *Amentaceæ*.

The characters are: that in the male the calyx is an ament oblong, imbricate every way, constructed of an involucre from the bud, consisting of scales one-flowered, oblong, flat, spreading: there is no corolla: petals none: nectary a gland cylindric, very small, truncate, melliferous, in the centre of the flower: the stamina have two straight, filiform filaments, longer than the calyx: anthers twin, four-celled—female: the calyx ament and scales as in the male: there is no corolla: the pistillum is an ovate germ, attenuated into a style scarcely distinct, a little longer than the scales of the calyx: stigmas two, bifid, erect: the pericarpium is an ovate-subulate capsule, one-celled, two-valved: valves revolute: the seeds numerous, ovate, very small, and crowned with a simple hirsute pappus or down.

The species cultivated are: 1. *S. triandra*, Long-leaved Three-stamened Willow; 2. *S. pentandra*, Bay-leaved Willow; 3. *S. vitellina*, Yellow Willow; 4. *S. amygdalina*, Broad-leaved Three-stamened Willow; 5. *S. hastata*, Halbert-leaved Willow; 6. *S. fragilis*, Crack Willow; 7. *S. Babylonica*, Weeping Willow; 8. *S. purpurea*, Bitter Purple Willow; 9. *S. Helix*, Rose Willow; 10. *S. fissa*, Basket Osier; 11. *S. rubra*, Green Osier; 12. *S. caprea*, Round-leaved Sallow; 13. *S. cinerea*, Cinereous-leaved Sallow; 14. *S. alba*, White Willow; 15. *S. viminalis*, Osier.

The first is naturally a tree thirty feet or more in height, but being one of the best osiers for the use of basket-makers is generally cut and

kept low: the bark of the stem and branches peels off spontaneously, almost like that of the plane-tree: the branches are upright, long, slender, pliable and tough, though somewhat brittle at their insertion; their bark is brownish and smooth: their leaves about three or four inches long, tapering away towards the base, and the breadth on each side the nerve is as nearly equal as possible; they terminate in a point; their margin is thickly serrate, the serratures incurved and rounded, a little glandular; both sides smooth, the under rather glaucous. Mr. Curtis remarks that it is not usual for willows to flower both in spring and autumn, but he has frequently found this species to do so. It is a native of many parts of Europe.

It may be admitted into ornamental plantations, the male catkins being very numerous, of a bright yellow colour, and of an agreeable scent: the male tree should on this account be preferred for ornament; and also because the females quickly shed their catkins and make a litter.

The second species is sufficiently well known by its broad odoriferous leaves, the serratures of which exude a copious yellow resin, and its numerous stamens, commonly about five to each flower. It frequently grows to a tree ten or twelve feet high, with a trunk as large as a man's thigh: the twigs are of a reddish colour tinged with yellow; the leaves are stiff, shining smooth on both sides, finely serrate with close numerous cartilaginous teeth; when full grown they are about three inches long, and an inch and half wide: their footstalks are short, broad, and sprinkled with glands: each scale in the male catkin has usually five stamens, but often six, and sometimes seven. These catkins are very sweet-scented. It is a native of Britain, &c.

The third is a middle-sized tree, much branched at the top: branches upright: the bark gray, chopped, cinnamon-coloured within, bitter and astringent: the female trees, when left to themselves, have pendent branches, but when lopped are stiff and straight: male catkins at first upright, then turned down; cylindrical, slender, serpentine, two inches long or more; on fruitstalks half an inch long: nectaries two: stamens two: female catkins from two to three inches in length, on fruitstalks from an inch to an inch and half long: the leaves alternate, upright, slightly serrate, with a yellowish midrib; they are about three inches long and one inch broad, but always broader in the female tree: the male tree is generally smaller and less common than the female. It is a native of the more temperate parts of Europe.

The shoots are used by basket-makers: the wood is white and very tough: the cotton will make ordinary paper, and may serve some of the purposes of genuine cotton: the bark may be used in dyeing, and medicinally in agues.

The fourth species never rises into a tree: the bark is deciduous: the leaves are shorter than in the first sort, scarcely two inches long, of a broadish ovate figure rounded at the base, by no means linear; oblique, the width of the two sides being unequal: the stipules are remarkably large, varying from a roundish to a half-heart-shaped form, crenate, deciduous: female flowers and capsules much as in that sort. It is a native of several parts of Europe.

The fifth is distinguished by its sessile ovate smooth leaves, sharply and very finely but scarce apparently serrate; and its subcordate stipules. It becomes a tree, but never tall: the branches are round, very straight, cinereous: the leaves hard, with very minute and scarcely visible serratures, cinereous beneath, but smooth on both sides, rigid, appendicled with two ovate entire leaflets. It is a native of Lapland, &c.

The sixth species grows to be one of the largest trees of the kind: the branches break off easily at the shoot of the preceding year: the leaves are large, four inches long, an inch and half broad, distinctly and deeply serrate, smooth and shining on the upper side, glaucous underneath: the stipules scarcely any, but instead of them the footstalks are dotted with prominent glands: the catkins have two or three fugacious leaves at the base of the peduncle. It is a native of the greater part of Europe, especially the northern parts, and is of quick growth, soon forming a shade in wet places; the males are fittest for this purpose. Bees are fond of the male flowers.

The seventh grows to a considerable size, as four feet and a half in circumference at three feet above the ground, and thirty feet in height. It is generally esteemed for its long slender pendulous branches, which give it a peculiar character, and render it a beautiful object on the margin of streams or pools: the leaves minutely and sharply serrate, smooth on both sides, glaucous underneath, with the midrib whitish; on short petioles: the stipules, when present, roundish or semilunar and very small; but more frequently wanting, and then in their stead a glandular dot on each side: the catkins axillary, small, oblong: in the male the filaments longer than the scale, with two ovate erect glands fastened to the base: the female, on two leaved peduncles, scarcely longer than half an inch. It is a native of the Levant.

The editor of Miller's Dictionary remarks that in No. 6817, Aug. 25 to 27, 1801, of the St.

James's Chronicle, there is the following paragraph, but on what authority he is not acquainted:—"The famous and admired weeping willow, planted by Pope, which has lately been felled to the ground, came from Spain, inclosing a present to the late Lady Suffolk. Mr. Pope was in company when the covering was taken off; he observed that the pieces of stick appeared as if they had some vegetation, and added, Perhaps they may produce something we have not in England." Under this idea he planted it in his garden, and it produced the willow tree that has given birth to so many others."

The eighth species is a bushy shrub three or four feet high, with long slender tough purple shining branches: the leaves some opposite, others alternate, nearly linear, but broadest upwards, serrate chiefly towards the summit, very smooth, glaucous beneath, destitute of stipules: the male catkins are very slender, scarcely an inch long, nearly sessile, consisting of many thick-set flowers, the uppermost of which expand first: the scales black at the tip, hairy: nectary a solitary gland opposite to each scale: the stamens one solitary simple, never dividing, bearing an orange-coloured double or four-lobed anther: the female catkins exactly like the male in size and form. It is particularly distinguished by the length as well as delicate slenderness of its twigs, and its subglaucous spurge-like leaves, but above all by their extreme bitterness when chewed. It is a native of many parts of Europe.

The ninth rises to the height of nine or ten feet, and is a small slender tree: in the form of its leaves it differs from the eighth, being more truly lanceolate and taper-pointed, by no means obovate: the female catkins are somewhat longer, and twice as thick, and stand on longer stalks: the germ is sessile, ovate and silky; but the style is considerably lengthened out, quite smooth and naked: the stigmas also, instead of being short and ovate, are linear and considerably elongated: the leaves are less glaucous beneath and not so bitter: the rose-like excrescences are more common at the ends of the branches in it; whence its name of Rose-Willow. It is a native of many parts of Europe.

The tenth species is a shrub four or five feet high, with upright flexible and very tough branches, of a yellowish ash-colour, often purplish: the leaves alternate, on footstalks, two or three inches long, minutely toothed or somewhat serrate, principally towards the top; smooth on both sides except when very young; dark green above, glaucous beneath: the stipules none: the catkins on short stalks, cylindrical,

blunt, first red, then yellow, flowering first at the top. It is a native of some parts of Europe on the sandy banks of rivers, flowering in April.

With us it is cultivated in the fens, and preferred to all other willows or osiers for basket-work.

The eleventh is a shrub which has the branches very long, slender, tough, smooth, gray or purplish: the leaves about four inches long when full grown, slightly toothed or serrate, by no means entire, of a bright green on both sides, smooth in general, but sometimes sprinkled with a few slender hairs beneath: the stipules, if present, linear-lanceolate, a little toothed; but generally wanting. It appears to be little known, though amongst the most valuable as an osier. It is a native of this country, &c.

The twelfth species often becomes a large tree: the branches when young palish, downy: the leaves slightly tapering to a point at both ends, above green and scarce sensibly downy, underneath pale green with a very thin wooliness: edge marked with some notches which are scarcely apparent unless carefully examined, but from the middle downwards evidently waved: the lower buds produce leaves, the upper ones catkins not leafy. It is useful for bees, as flowering early.

The thirteenth is more than six and sometimes near twelve feet high; in exposed boggy grounds spreading more, but not rising so high: the leaves alternate, rude, rugged, wrinkled and green above, beneath rough with hairs, the veins indistinct, the edge serrate, on loose petioles two lines in length: stipules in shape of half a heart, on each side serrate with three glands: the catkins brownish, placed below the leaves, on a peduncle with a few small spear-shaped leaflets. It is the common Sallow, and a native of Europe, flowering in April.

The fourteenth species, when suffered to grow without lopping, becomes a large and lofty tree: it is of quick growth, but when lopped soon decays: the trunk is straight with a gray rough bark full of cracks: the branches numerous, upright, but diffused, gray or brownish green, the upper ones often dusky red: the inner bark is green: the leaves sharply and elegantly serrate; shining but pubescent above, white and silky underneath: the male catkins cylindrical, blunt, from an inch and half to two inches in length, four lines in breadth, on peduncles half an inch long: the stamens two: the nectaries two, one before the stamens obcordate, the other behind them oblong: the female catkins slender, cylindrical, two inches long, three or four lines broad, on peduncles near an inch in length. It

is a native of Europe, flowering in April and May. Its wood is white, light, and tough.

The fifteenth is a very tall, slender, obsequious, quick-growing shrub: the leaf and flower-buds distinct: the leaves rolled back at the edges before they unfold. It is frequently arborescent: the bark grayish, smooth, with here and there a crack: the branches very long, straight, slender, tough: the leaves, especially the lower ones, a span long or more, waved at the edge: the male catkins ovate or oblong, from an inch to an inch and half in length, three or four lines in breadth, on very short peduncles: stamens two: nectary one: the female catkins ovate-oblong or cylindrical, of the same length with the male, half an inch broad; peduncle two lines long: the leaves being silvery underneath, the nectary in the male flower being long and slender, and the style in the female flower being very long, are sufficient marks to distinguish it by. It is a native of most parts of Europe. It is the true Osier.

There are a vast number of varieties in cultivation for the uses of the basket-maker. Evelyn has enumerated three vulgar sorts: one of little worth, being brittle, and very much resembling the Sallow, with reddish twigs, and more greenish and rounder leaves: a second, called Perch, of limber and green twigs, having a very slender leaf: the third totally like the second, only the twigs not altogether so green, but yellowish. This is the very best, he says, for use, tough and hardy. The most usual names applied to them by basket-makers about London are: the Hard-Gelster, the Horse-Gelster, Whyning, or Shrivelled-Gelster, Black-Gelster, in which Suffolk abounds. Then the Goldstones, the Hard and Soft, Brittle and worst of all the Goldstones; the Sharp and Slender-topped Yellow Goldstone; the Fine Goldstone. Then there is the Yellow Osier, the Green Osier, the Snake or Speckled Osier, Swallow-tail and Spaniard. To these, the editor of Miller's Dictionary says, may be added the Flanders Willow, which will arrive to be a large tree—with these coopers tie their hoops to keep them bent. Lastly, the White Swallow, used for green-work; and if of the toughest sort, to make quarter can-hoops. It is further suggested, that innumerable varieties are cultivated in the osier-grounds for the basket-makers; and the same frequently under different names in different places, so that it would be difficult and of little use to enumerate them; but that the Dutch and Wire Osiers are esteemed about London. The true Velvet Osier, which is a valuable sort, has, it is said, been made out to be distinct from the *viminalis*.

Culture.—All these plants are capable of being readily increased by cuttings of the young shoots of one or two years old, in lengths of half a yard or two or three feet; and those of several years growth in truncheons or sets, of from three or four to five or six feet long, according to the purposes for which they are designed, which strike root most readily in low moist soils. The proper season for planting them out is any time in open weather, from the beginning of autumn till March; but the early autumn and spring months are the best, according as the soil may be more moist. In the planting, a long iron-shod dibble is used for the smaller cuttings, and an iron crow for making holes for the larger sets, or holes may be made with a spade for very large long pole-cuttings; though some use no instrument in planting the smaller cuttings, but sharpen the ends of them, and thrust them into the ground, especially in soft land; but as this method is apt to force off the bark from the lower part of the cutting, it is best to cut the bottom of each cutting even, and plant them with some instrument in the above manner.

These sets are planted for different purposes; as for timber trees—to form osier grounds—to cut for poles,—for pollards for lopping, &c.

When they are intended to be raised for timber, the larger growing sorts, such as the white-yellow, and purple, or red willows, &c. should be chosen, taking cuttings of the strong young shoots, which should be planted at once where they are to remain, in any low marshy, or rather moist situation, where they grow with great rapidity. The ground should be prepared by proper digging, or ploughing, as may be most convenient, and then a quantity of cuttings of the strong young shoots, of one or two years' growth, cut to half a yard or two feet lengths, should be provided and planted in rows, only six feet asunder, and three or four distant in the rows, that they may draw each other up fast in growth, and allow for a gradual thinning, each cutting being inserted two parts of three into the ground. They soon emit roots, and shoot strongly at top in spring and summer; but to have them run up with clean stems for full standards, all should be cleared away but one of the strongest leading shoots for a stem, which should be suffered to run up at full length in its future growth. After a few years, when the trees approach one another, they should be thinned for poles, &c.; repeating the thinning a few years afterwards, according as the branches of the different trees interfere, leaving them at last about twelve or fifteen feet asunder, to attain their full growth: in this way they draw each other up very expeditiously with straight handsome stems, to forty

or fifty feet in height, or more; and in twenty or thirty years become fit to sell as timber.

When intended to form osier grounds for low stools, for producing twigs annually for the basket-makers, they should be planted in rows two or three feet asunder, and be always kept to low stools a foot high, in order to force out a more plentiful annual crop of twigs and rods, proper for use in one summer's growth. For this purpose, waste boggy land in the sides of large rivers are the most proper, both in respect to the soil, and the conveyance of the wands.

These situations should be dug over or ploughed, for the reception of the osiers: then, in the proper season, as above, a sufficient quantity of osier sets of different sorts, in cuttings of the one or two years old shoots, should be formed into two feet or two feet and half lengths, planting them in lines two feet and half distance, inserting each cutting from ten or twelve to fifteen inches into the ground, leaving the rest out to form the stool, and let them be two feet and half distant in each row: having thus formed the plantation, the cuttings will root firmly in the spring, and shoot at top tolerably strong in summer, each stool generally throwing out several shoots, of an erect growth. During the first summer, all large weeds should be kept down, that the stools may have full scope to produce the first shoots as strong as possible, which, by the end of autumn, will probably be advanced some considerable length; and if much wanted may be cut in the following winter or spring; but for full plantations they should generally be suffered to continue their growth for two years, till the stools are firmly rooted and become strong; then be cut down with all the tops close to the heads of the stools, which serve for poles, &c. Next year the stools shoot out strong, a numerous crop of twigs and rods, fit for cutting for the basket-makers in the winter following; and the stools still remaining, continue to furnish an annual crop fit for cutting every winter: the twigs when cut should be sorted in sizes, tied in bundles, and stacked up for use.

Where intended to cut for poles, the plantations of stools may be made in any waste watery situations, as along the sides of brooks, rivers, watery ditches, and other similar situations; to cut every three, four, five, or six years, according to the purposes for which they may be employed.

- In forming them, a quantity of sets, of two years old shoots, in cuttings about two feet and half long, should be provided, and planted in rows a yard asunder, introducing each cutting two parts of three into the ground; they readily grow, and each sends out several erect shoots, which,

in three or four years, will become large poles fit to be cut for use.

Large cuttings or truncheons, three or four feet long, may likewise be thrust down along the sides of rivers, brooks, ditches, &c. which will often take root, and shoot out strongly at top for poles.

When designed for pollard standards to cut over for poles, for hurdles, &c. also for fuel, every fifth, sixth, or seventh year, the sets or cuttings may be obtained in plenty from the loppings of any old pollard willows, &c. choosing the large straight poles, cut from about seven or eight to nine or ten feet lengths, which should be planted either with an iron crow, or some other similar implement, forced into the ground to make wide holes, two feet or two and a half deep, for their reception: or, if the ground be stubborn, the holes should be dug with a spade to that depth, planting one set in each hole, placing them from a foot and half at least to two feet and half in the ground, leaving six, seven, or eight above for the stem: these sets, though so large and long, if planted in moist places, readily strike root, and shoot out at top the following spring and summer, into many erect branches, which, after four or five years growth, become fit to lop for poles, &c. The trees thus continue to afford a lopping as above, or may be suffered to grow larger, according to the purposes for which the loppings may be wanted.

When for the purpose of forming hedges quickly, either as fences, blinds, or shelter, cuttings, either of strong young shoots, formed in two or three feet lengths, and planted in a row half a foot asunder, and twelve to fifteen or eighteen inches deep, may be employed, or larger truncheons of several years growth, cut into sets, two, three, four, or five feet long or more, be used: in either case, when the sets have made the first year's shoot, the shoots may be plashed together in winter, both to stiffen the hedge and give it a thicker form, and afterwards be kept regular by clipping it annually, or suffered to take its own natural growth.

But, in order to form a willow hedge as quickly as possible, large straight sets of five or six feet long may be used, planting them chequer-ways, placing each set half a yard in the ground, leaving three or four feet above; which, being arranged, cross one another in the above manner; and ranged all of an equal height, they at once form a good firm fence.

And where a speedy fence is wanted, by way of blind or shelter, a quantity of loppings, five, six, or seven feet long, well furnished with lateral branches to the bottom, may be provided and

planted in a deepish trench, pretty close together, which soon grow, and form a sort of fence immediately.

When for twigs for garden uses, a moist situation should be chosen, and a quantity of the most pliant kind of osier sets, or cuttings of the young shoots, half a yard or two feet long, should be provided and planted in rows, two parts of three into the ground. They grow freely, and furnish plenty of twigs every year, managing them as those in the osier plantations.

The after-culture in all these cases is principally the keeping down large weeds the first and second years after planting, but which is more particularly necessary in the plantations of young low cuttings, till they are a little advanced in their growth.

When intended for nursery collections, all the different sorts should be kept, being raised from young cuttings of a year or two old, in half-yard or two feet lengths, and planted in rows, two or three feet asunder, to grow till wanted for use.

Some of these sorts of willows may be used with good effect, as ornamental trees on the sides of ponds or other places, especially white, yellow, purple, sweet, almond-leaved, and weeping kinds, being disposed thinly in large out-plantations; but the Babylonian or Weeping Willow, for its curious pendulous growth, demands attention in a particular manner, and should be disposed singly, or detached, both by the side of water, and in spacious openings of grass ground, also near grottoes, cascades, caves, ruins, &c.

SALLAD HERBS, the different sorts of esculent plants from which herbs for sallads are collected. These by different sowings, plantings, &c. are obtained at all times of the year; but the most generally esteemed sorts may be comprised under the heads of Large, Small, and Occasional Sallad Herbs.

The first consist chiefly of the different sorts of lettuces; the different sorts of endive, and all the varieties of celery, which sorts are in the best perfection for use when arrived at the full growth; any of which may be eaten as a sallad alone, or all mixed together, or with a proper quantity of small sallading, especially in winter and spring; as the small sallading being of a warm nature renders the sallad more grateful and wholesome. Lettuces are generally esteemed most in summer, when full grown and firmly cabbaged, but may be used at all seasons. The endive and celery are excellent for autumn and winter sallads, being in full perfection from September to the end of November, when they are full grown and finely blanched, and often continuing in to-

lerable perfection all winter and spring. See **LACTUCA**, **CICHORIUM**, and **APIUM**.

The second sorts are cresses, mustard, radish, rape, and some others; in all of which herbs, the young leaves are the useful parts for the purpose of sallad, and are always in the best perfection when quite young, as a few days, or a week old at most, while in their first leaves; cutting them up, stalks and top together, close to the ground, as when used thus quite young they eat exceeding tender, with an agreeably warm relish, but become too hot by age. See **SMALL SALLAD HERBS**.

The last sorts are, principally corn sallad, or lamb's lettuce—purslane—spear-mint—watercress—borage and borage-flowers—nasturtium-flowers and the young leaves—chervil—burnet, and sometimes red-cabbage—radishes—red beet-root—finocchio, or Azorian fennel—sorrel—tarragon—young onions—cives—and sometimes horse-radish, incorporated with other herbs; most of which sorts are occasionally used in composition with other sallad herbs, and some alone as a sallad, such as red-cabbage, watercress, young borage, &c. See their respective genera.

SALLOW. See **SALIX**.

SALSOLA, a genus containing a plant of the shrubby evergreen kind.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Holostaceæ*.

The characters are: that the calyx is a five-parted perianth: segments ovate, concave, permanent: there is no corolla, unless the calyx be called so: the stamina have five very short filaments inserted into the segments of the calyx: the pistillum is a globular germ: style three-parted or two-parted, short: stigmas recurved: the pericarpium is an ovate capsule, wrapped in the calyx, one-celled: the seeds single, very large, spiral.

The species cultivated is *S. fruticosa*, Shrubby Saltwort, or Stone-Crop Tree.

It has the stem about two feet high or more, woody, erect, round, very much branched; the branches also erect, and thickly clothed with alternate, sessile, semi-cylindrical, bluntish, fleshy, even, almost upright, rather glaucous leaves: the flowers inconspicuous, axillary, sessile, solitary, green; with three small, concave, scarious bractes. The leaves have an herbaceous flavour, with a slight degree of salt and some acrimony. It forms an elegant evergreen shrub, flowering in July and August. It is a native of France, &c.

Culture.—This plant may be increased by layers or cuttings, though with difficulty in the latter method.

The young branches should be laid down in the spring, and when well-rooted, in the following autumn, be taken off and planted out where they are to remain, a warm sheltered situation being provided for the purpose.

Though these plants are inhabitants of the sea shores, they may be introduced in the borders and clumps of the shrubbery with other evergreens.

SALVIA, a genus containing plants of under-shrubby, herbaceous, and shrubby kinds.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Verticillatæ*.

The characters are: that the calyx is a one-leaved perianth, tubular, striated, gradually widening and compressed at the top: mouth erect, two-lipped; lower lip two-toothed: the corolla one-petalled, unequal: tube widening at the top, compressed; border ringent, upper lip concave, compressed, curved inwards, emarginate; lower lip wide, trifid, middle segment larger, roundish, emarginate: the stamens have two filaments, very short; two threads are fastened transversely to these almost in the middle, on the lower extremity of which is a gland, on the upper an anther: the pistillum is a four-cleft germ: style filiform, very long, in the same situation with the stamens: stigma bifid: there is no pericarpium. Calyx very slightly converging, having the seeds in the bottom of it: the seeds four, roundish.

The species cultivated are: 1. *S. officinalis*, Garden Sage; 2. *S. grandiflora*, Broad-leaved Garden Sage; 3. *S. triloba*, Three-lobed Sage, or Sage of Virtue; 4. *S. sclarea*, Common Clary; 5. *S. argentea*, Silvery-leaved Sage or Clary; 6. *S. verbenaca*, Vervain Sage or Clary; 7. *S. Indica*, Indian Sage or Clary; 8. *S. Horminum*, Red-topped Sage or Clary; 9. *S. glutinosa*, Yellow Sage or Clary; 10. *S. Mexicana*, Mexican Sage; 11. *S. Canariensis*, Canary Sage; 12. *S. Africana*, Blue-flowered African Sage; 13. *S. aurea*, Gold-flowered African Sage; 14. *S. pomifera*, Apple-bearing Sage; 15. *S. formosa*, Shining-leaved Sage.

The first is a branching shrub, about two feet in height: the younger branches are tomentose and whitish: the leaves are wrinkled, cinereous white or tinged with dusky purple, on very short petioles, sometimes eared at the base: the flowers terminating, in long spikes composed of six-flowered whorls, approximating, yet distinct. It is a native of the South of Europe and Barbary.

The varieties are: the Common Green Sage, the Wormwood Sage, the Green Sage with a variegated leaf, the Red Sage, the Red Sage with a

variegated leaf, the Painted or Parti-coloured Sage with red leaves striped with white, or white red and green mixed, found, says Johnson, "in a country garden by Mr. John Tradescant, and by him imparted to other lovers of plants." There is also Spanish or Lavender-leaved Sage, in which the leaves are linear-lanceolate, very narrow and quite entire, in clusters on the side of the stalks; they are very hoary, and the branches are covered with a hoary down: the leaves on the upper part of the stalk are narrower than those of Rosemary; the flowers grow in closer spikes, and are of a light blue colour.

But the variety with red or blackish leaves is the most common in cultivation; and the Wormwood Sage is in greater plenty than the common green-leaved Sage.

In the second species the stalks do not grow so upright as those of the common Sage; they are very hairy, and divide into several branches: the leaves are broad, woolly, on long petioles, serrate, and rough on the upper surface: the leaves on the flower-stalks are oblong-ovate, on shorter petioles, and very slightly serrate: the whorls are pretty far distant, and few flowers in each; they are of a pale blue, and about the same size with those of the common sort. It flowers in June, and in good seasons the seeds ripen in autumn. This sage is preferred to all the others for tea. It is often called Balsamic Sage.

The third has the leaves narrower than those of the common sort; they are hoary, and some of them are indented on their edges towards the base, which indentures have the appearance of ears. The spikes of flowers are longer than those of the two preceding sorts, and the whorls are generally naked: the flowers are smaller, and of a deeper blue than those of the Common Sage. It is a native of the South of Europe.

The fourth species has the lower leaves large, in good ground seven or eight inches long, and four broad at the base, ending in blunt points: the stems large and clammy, about two feet high, with leaves of the same shape, but smaller, and sending out small opposite side branches: the flowers in loose terminating spikes, composed of whorls, of a pale blue colour. It is biennial, and a native of Syria, &c. flowering from July to September.

It is observed, that "a wine is made from the herb in flower boiled with sugar, which has a flavour not unlike Frontinac."

The fifth has the leaves of a thick consistence, having several irregular indentures on their borders: the stem near a foot and half high, sending out two or four branches near the bottom, which grow erect: the whorls of flowers large,

towards the top barren. It is a native of the island of Candia, and biennial, flowering in June.

The sixth has a perennial brown root, the thickness of the middle finger, striking deep into the earth, and furnished with numerous fibres: the stems nearly upright, two feet high, set with horizontal somewhat viscid hairs, purplish, especially at the joints: the root-leaves on long petioles, varying in form, oblong, rounded at the end, sometimes a little pointed, not unfrequently heart-shaped at the base, but more commonly the leaf runs down on each side the footstalk, and to a greater length on one side than on the other, very slightly hirsute, on the margin irregularly waved and serrate or toothed, paler beneath, veiny and marked with small glandular concave dots: stem-leaves somewhat remote, the lowermost on short footstalks, the uppermost sessile: the flowers in whorls, almost naked, containing about six flowers. It is a native of all the four continents, flowering during the whole summer from June, and even in October.

The seventh has the lower leaves heart-shaped, acutely crenate, of a thick consistence, seven or eight inches long, and four broad at the base, where they are eared: the stem four feet high, having two or three pairs of smaller leaves on the lower part at the joints: the upper part, for the length of two feet, has whorls of flowers, at two or three inches distance from each other, without any leaves under them: the calyx is hairy and blunt: the helmet of the corolla arched, erect and blue, terminating in a blue point; the two side segments of the under lip are of a violet colour; the middle segment, which is indented at the point, is white, and curiously spotted with violet on the inside; the two side lobes turn yellow before the flower drops. It is a native of India, flowering from May to July.

The eighth has the stems erect, about a foot and half high: the leaves shaped like those of the common Red Sage, gradually diminishing in size to the top: the stems have whorls of small flowers, and are terminated by clusters of small leaves, and forming two varieties; one with purple and another with red tops. For the sake of this comia they are preserved in gardens for ornament. They flower in June and July, and their seeds ripen in the autumn. It is a native of the South of Europe.

The ninth has an abiding root, composed of strong woody fibres: the leaves four inches long, and three broad at the base, of a pale yellowish green colour, upon footstalks three or four inches long: the stems strong, near four feet high, having smaller leaves below, and the upper part

VOL. II.

closely set with whorls of large yellow flowers. The whole plant is very clammy, and has a strong scent, somewhat like common Garden Clary. The flowers are used in Holland to give a flavour to the Rhenish wines. It is a native of Germany, &c. flowering from June to November.

The tenth has the stem shrubby, eight or ten feet high, sending out slender four-cornered branches of a purplish colour: the leaves thin, pale green, and hairy on their under side, on long slender footstalks: the flowers in close thick spikes at the end of the branches, having a fine blue colour. It is a native of Mexico, flowering from May to July.

The eleventh has the stem shrubby, five or six feet high, dividing into many branches covered with a flocky down: the leaves three inches and a half long, and an inch and half broad at the base, where are two acute angular ears: petioles long and woolly: the top of the stalk branches out into many footstalks, forming a sort of panicle: the flowers are of a light blue colour, and are ranged in whorled spikes, having two small leaves under each whorl. It is a native of the Canary Islands, flowering from June to September.

The twelfth rises with a shrubby stalk four or five feet high, dividing into branches: the leaves are ovate, of a gray colour: the flowers come out in whorls towards the end of the branches; they are of a fine blue colour, larger than those of the common Sage, appear in succession most of the summer months, and those which come early are often followed by seeds ripening in autumn. It is a native of the Cape.

The thirteenth also rises with a shrubby stalk seven or eight feet high, covered with a light-coloured bark, sending out branches the whole length which grow almost horizontally: the leaves are of a gray colour: the flowers, in thick short spikes at the end of the branches, are very large, and of a dark gold colour. It is a native of the Cape, flowering from May to November.

The fourteenth has the stem shrubby, four or five feet high, dividing into several branches: the flowers of a pale blue colour: the branches have often punctures made in them by insects, producing protuberances as big as apples, in the same manner as galls upon the Oak, and the rough balls upon the Briar. It is remarked by Martyn, that the common Sage has the same excrescences in the island of Candia or Crete, and that they carry them to market there under the name of Sage Apples. It was found at Candia.

The fifteenth has the stem suffruticose, the height of a man, upright, brachiate, somewhat knotty, loosely chapped, ash-coloured: the

3 C

branches and branchlets opposite, spreading, four-cornered, naked at the base, rufous: shoots four-grooved, green at the top, clammy: the leaves spreading, acute (in the garden bluntish), crenate-serrate, somewhat wrinkled, veined, with the midrib and veins prominent only beneath, subcoriaceous, greenish, but paler on the back: petiole scarcely half as long as the leaf, round on one side, grooved on the other: flowers very many, from the axils of the shoots, in a sort of whorl, in the garden commonly five together, the two lower of which are later: they are on short, spreading, one-flowered peduncles, jointed at the top. It is a native of Peru, flowering most part of the summer.

Culture.—These plants are in most of the sorts raised without much difficulty.

Culture in the Sage Kind.—This in all the varieties may be effected by slips or cuttings of the young shoots from the sides of the branches, sometimes also by bottom rooted off-sets, and likewise by seed. Slips both of the former and same year's growth may be used.

Those of the first sort may be employed in April, but the latter not till May, or later: these, however, most readily strike root, and assume a free growth.

In either case, moist weather should be chosen; and having recourse to some good bushy plants, a proper quantity of the outward robust side shoots, about five, six, or seven inches long, should be slipped off, trimming off all the lower leaves, then planted out in some shady border, with a dibble, in rows half a foot asunder, putting them down almost to their tops, giving water directly, to settle the earth close, as well as to promote an early emission of root-fibres, and repeating the waterings occasionally in dry weather: the slips in general soon emit fibres, and shoot freely at top: when they have a tendency to spindle up with slender shoots, or run up to flower, it is proper to top them short in order to force out laterals below, to assume a bushy growth: they mostly form tolerably bushy plants by the autumn, when, or in the spring following, they may be removed, with balls of earth about their roots, and planted where they are to remain, either in four-foot beds, or in continued rows, a foot and half asunder, if designed as a close plantation for use: those designed for the pleasure-ground should be disposed in the borders, &c. so as to afford variety.

Where there are rooted off-sets, they may be slipped off separately with the fibres to them, either as the plants stand in the ground, or the bunches of plants taken up and divided into as many separate slips as are furnished with roots,

being planted out at once where they are to remain.

The plants raised from young slips generally form the strongest and most bushy plants.

In raising these plants from seed, which is but seldom practised, it should be sown in April, in a bed of light rich earth, raking it in: the plants soon come up; and when about two or three inches high, should be pricked out, the strongest in nursery rows, half a foot asunder, to gain strength till the autumn or spring following, and then planted out with balls where they are to stand.

In the after-culture of this species and varieties, all that is requisite is the keeping them clean from weeds in summer, cutting down the decayed flower-stalks in autumn, and slightly digging between the rows in the same season, to keep them clean and decent during the winter, &c. But where this digging is not done in the autumn it should not be omitted in the spring.

The leaves of the Sage should be gathered with care and attention, not to cut the tops too close, to render the plants naked and stubby, especially when late in autumn and winter; in which they would be more liable to suffer from severe frost than when the head is preserved somewhat full and regular: besides, in this state the plants continue longer in a prosperous free growth.

When, in any old plantation, naked, stubby, or decayed parts occur, they should be cut out, and any straggling irregular growths reduced to order by occasional pruning in spring or summer, by which the plants will more readily emit fresh shoots and form full heads.

Fresh plantations of Sage should be formed as the old ones decline.

In continuing them where the ground is much impoverished, a little dry rotten dung should be pointed in lightly, to give more vigour to the plants.

Culture in the Clary Kind.—These in the herbaceous kinds are easily raised from seed, and in the perennial sorts by parting the roots.

The seed should be sown in March, in any bed or border of common earth, raking it in; and when the plants have got leaves of two or three inches growth, they should be planted out in showery weather, in rows eighteen inches distant, and at the same distance in the lines: they soon strike root, and grow large, furnishing large leaves, fit for use in autumn, winter, and the following spring.

The perennial sorts are raised from seed in the same manner, setting the young plants out in the summer in nursery-rows till autumn, when they should be planted out into the borders, &c.

The annual sorts may be sown in spring in the borders, in patches to remain.

The roots in the perennial kinds may be parted in autumn, or early in the spring, and planted out where they are to remain.

Culture in the tender Shrubby Kinds.—These are easily increased by cuttings of the young shoots; they should be planted in pots in the spring, and plunged in a hot-bed, where they soon emit roots at bottom and shoots at top, and should be gradually hardened to the full air: but cuttings planted in summer will often strike without the aid of a hot-bed when planted either in pots or in a bed of natural earth, under frames and lights, or covered close with hand-glasses, and shaded from the mid-day sun, being occasionally watered.

The young plants should afterwards be potted off separately, and managed as other shrubby exotics of the green-house.

The last sort requires a warm dry green-house in winter, and to be very sparingly watered. See GREEN-HOUSE PLANTS.

Some of the sorts are useful as culinary plants, others for the purpose of ornament in the borders, &c. and the tender sorts in green-house collections.

SAMBAC. See JASMINUM.

SAMBUCUS, a genus containing hardy deciduous trees, shrub and herbaceous perennials.

It belongs to the class and order *Pentandria Trigynia*, and ranks in the natural order of *Dumosæ*.

The characters are: that the calyx is a one-leaved perianth, superior, five-parted, very small, permanent: the corolla one-petalled, rotate-concave, five-cleft, blunt: segments reflex: the stamina have five awl-shaped filaments, the length of the corolla: anthers roundish: the pistillum is an inferior, ovate, blunt germ: style none; but instead of it a ventricose gland: stigmas three, blunt: the pericarpium is a roundish one-celled berry: the seeds three, convex on one side, angular on the other.

The species cultivated are: 1. *S. nigra*, Common Elder; 2. *S. racemosa*, Red-berried Elder; 3. *S. Ebulus*, Dwarf Elder; 4. *S. Canadensis*, Canadian Elder.

The first species grows to a bushy tree twelve or sixteen feet in height, much branched, and covered with a smooth gray bark when young, which becomes rough on the trunk and older branches: the wood is hard, tough, yellow, polishing almost as well as the box-tree; the younger branches containing a very large proportion of medullary matter or pith: the leaves opposite, unequally pinnate: leaflets commonly

five, smooth, nearly equal at the base, with very small or no stipules: the cymes terminating, dividing into five principal branches, and many small ones: the flowers cream-coloured, with a sweet but faint smell, especially when dried. It is a native of Britain and many other parts of Europe; also of Africa, Japan, &c., flowering in May and June.

There are varieties with white or green berries, with variegated leaves; and the Parsley-leaved Elder, which has the leaflets narrower, and cut into several segments, which are again deeply indented on their edges regularly, in form of winged leaves: the stalks are much smaller, and the shoots are short; the leaves have not so strong an odour, and the berries are a little smaller.

There are also the Gold-striped-leaved, the Silver-striped-leaved, and the Silver-dusted Elder.

The second species sends up many shrubby stalks from the root, rising ten or twelve feet high, and dividing into many branches, which are covered with a brown bark: the leaves are opposite; the lower generally composed of two pairs of leaflets, terminated by an odd one, shorter and broader than those of the first, and deeply serrate; the upper have frequently but three leaflets; they are of a pale green colour and pretty smooth: the flowers are of an herbaceous white colour, appearing in April, and sometimes succeeded by berries, which are red when ripe. It is a native of Germany, Switzerland, Italy, &c.

The third has a creeping root: the stems herbaceous, three feet high, upright, roundish, grooved, leafy, somewhat enlarged at the joints, purplish, branched above; the branches opposite and upright: the leaves opposite, unequally pinnate, dark green, smoothish: leaflets four to six pairs, ovate-lanceolate, veined, acute, serrate, unequal, and generally glandular at the base, smooth above, downy with a slight roughness underneath, and whiter; the lowermost often lobed: the stipules large, leafy, serrate, sometimes accompanying a pair of leaflets as well as the whole leaf: the cyme terminating in three principal branches, and those dividing into many others, hairy and many-flowered: all the flowers pedicelled. It is a native of many parts of Europe.

It was formerly called Wallwort or Walewort, and Danewort, and differs from the first sort in being herbaceous, in having a creeping root, and narrower leaflets, more numerous, and sometimes lobed.

There is a variety with but leaves in which the roots do not creep so much, nor the stems rise

so high: the leaves have seldom more than seven leaflets, and towards the top only five, longer and narrower than in the above, deeply cut on their edges, and ending with winged acute points.

The fourth species rises to the height of twenty feet in its native situation, but here, it is seldom much more than half that height: the leaves have generally seven or nine leaflets, which are longer and narrower than those of the first sort: the berries are smaller, of the same black colour, but not so full of juice; nor have the leaves so strong a scent: it is shrubby, but commonly perishes above ground in winter: the cymes are of the same structure as in the first; and the stipules are filiform and truncate, as in that, not expanded into leaflets, as in the third: the berries are reddish, and said to be eatable. It is a native of North America, flowering from June to August.

Culture.—The first and second sorts may be readily increased from cuttings, or by sowing their seeds; but the former being the most expeditious method, it is generally practised. The season for planting the cuttings is any time from the autumn to the spring; in doing of which, there is no more care necessary than to thrust them about six or eight inches into the ground, as they take root readily, and may afterwards be planted out where they are to remain, which may be upon almost any soil or situation, as they are extremely hardy: if their seeds be permitted to fall upon the ground, they often produce plenty of plants the succeeding summer.

They are often planted for fences, on account of their quick growth; but as their bottoms become naked in a few years, they are not by any means proper for that purpose. In this intention the cuttings should be planted in one or two rows, where they are to remain.

This sort of plants should not be planted near habitations, as at the season when they are in flower they are said to emit such a strong scent as to occasion violent pains in the heads of those who abide long near them.

The first sort succeeds in any soil or situation.

The third is increased rapidly, wherever it is once planted, by its creeping roots; and the fourth puts out roots from cuttings almost as easily as the common sort; but being liable to injury from severe frosts, it should be planted in a sheltered situation, and rather dry soil.

All the sorts afford diversity in large ornamental plantations, the common sorts being only thinly introduced.

The fruit of the common sort is frequently made use of for the purpose of making wine from it.

SAND, an earthy substance that is frequently made use of in the culture of different sorts of flowers and plants which require a dry soil.

SAND-BOX TREE. See HURA.

SANGUINARIA, a genus containing a plant of the low herbaceous flowering kind.

It belongs to the class and order *Polyandria Monogynia*, and ranks in the natural order of *Rhoeadeæ*.

The characters are: that the calyx is a two-leaved perianth, ovate, concave, shorter than the corolla, caducous: the corolla has eight petals, oblong, blunt, spreading very much, alternately interior and narrower: the stamina have very many filaments, simple, shorter than the corolla: anthers simple: the pistillum is an oblong compressed germ: style none: stigma thickish, two-grooved with a streak, height of the stamens, permanent: the pericarpium is an oblong capsule, ventricose, sharp at both ends, two-valved: the seeds very many, round, acuminate.

The species is *S. Canadensis*, Canadian Sanguinaria, Bloodwort, or Puccoon.

It has a tuberous, thick, fleshy root, placed transversely, with several slender fibres descending from it, of a reddish saffron colour, and yielding a juice of the same hue, which is bitter and acrid, and flows also from the leaves and footstalks when cut. In the spring the root puts forth slender round smooth stems, palish green or brownish tinged with purple, each terminated by a little conical head, which expands into a white flower of eight petals, at first concave, then flat, and finally rolled back so as to be convex, marked with slender streaks: filaments white, with saffron-coloured anthers. When the flowers are about expanding, a single leaf comes out upon each flower-stalk, at first small, compressed, and protecting the flower with its foot-stalk; but afterwards becoming larger, and unfolding into lobes, like those of the fig, which are thickish, smooth, internally of a deep glaucous green, externally of a whitish glaucous colour with frequent veins, most conspicuous on the outside; on petioles which are flat and slightly grooved on the inside, and convex on the outside. Three or four flower-stems arise from each root, and are surrounded at the base by oblong, membranaceous, tender, striated scales: the root, leaves, and flowers have no smell. It is a native of America, and flowers here in the beginning of April.

There are varieties with single flowers, with semi-double flowers, and full flowers.

Culture.—This plant is readily increased by parting the roots, and planting them out in the

borders or other places where they are to remain, in the autumnal season, when the leaves and stems decay.

They should have a loose soil, with a mixture of bog earth and rotten leaves, and sheltered situation, not too much exposed to the sun: the roots should not be parted oftener than every two years.

They afford variety in the borders, clumps, and other parts among other low-growing bulbous-rooted plants.

SANTOLINA, a genus comprising plants of the low, under shrubby, evergreen, and herbaceous kinds.

It belongs to the class and order *Syngenesia Polygamia Æqualis*, and ranks in the natural order of *Compositæ Discoideæ*.

The characters are: that the calyx is common, hemispherical, imbricate: scales ovate-oblong, acute, pressed close: the corolla compound uniform, longer than the calyx: corollæ hermaphrodite, equal, numerous; proper one-petalled, funnel-form: border five-cleft, revolute: the stamens have five capillary filaments, very short: anther cylindrical, tubulous: the pistillum is a four-cornered oblong germ: style filiform, length of the stamens: stigmas two, oblong, depressed, truncate: there is no pericarpium: calyx unchanged: the seeds solitary, oblong, four-cornered: down none: the receptacle chaffy, flattish: chaffs concave.

The species are: 1. *S. Chamæcyparissus*, Common Lavender-cotton; 2. *S. rosmarinifolia*, Rosemary-leaved Lavender-cotton; 3. *S. alpina*, Alpine Lavender-cotton; 4. *S. anthemoides*, Chamomile-leaved Lavender-cotton.

The first has a shrubby stalk dividing into many woody branches, with slender hoary leaves, indented four ways, and having a rank strong odour when handled: the branches divide towards the top into several slender stalks, the lower parts of which have a few small leaves of the same shape as the others, but naked above, and terminated by a single flower, composed of sulphur-coloured fistular florets, without any ray. It rises nearly three feet high in a dry soil and sheltered situation. It is a native of the South of Europe; as Spain and Italy.

There are several varieties of the Hoary Lavender-cotton, which branches out like the common sort, but seldom grows so tall: the branches are divided into a great number of stalks, which are short, hoary, and below set very closely with shorter, thicker, and whiter leaves: the flowers are much larger, and the brims of the florets more reflexed, and of a deeper sulphur-colour. It grows naturally in Spain.

The Creeping Lavender-cotton, which is of still lower stature, seldom rising more than fifteen or sixteen inches high: the branches spread horizontally near the ground, and have shorter leaves than either of the former; they are hoary, and finely indented; the stalks are short, and are each terminated by a single flower of a bright yellow colour, and larger than those of the common sort.

And the dark-green Lavender-cotton, which rises higher than these: the branches are more loosely disposed, and more diffused; are more slender, smooth, and have very narrow long leaves of a deep green colour, indented only two ways; the stalks are slender, naked towards the top, and terminated by single flowers of a gold colour.

The second species is herbaceous, scarcely suffruticose: the leaves at the edge on both sides crenulate with tubercles in two rows, but on the flowering-stalk linear, toothleted on each side at the top: the peduncles long, terminating, one-flowered. According to some, the stalks are shrubby, about three feet high, sending out long slender branches, with single linear leaves about an inch and half long, pale green and entire: the stems terminated by large, singular, globular flowers of a pale sulphur-colour. It is a native of Spain, flowering from July to September.

There is a variety in which the branches are shorter, thicker, and closer set with leaves; which come out in clusters, are shorter, and blunt: the flower-stalks are sparsely disposed, and have leaves to their top: the flowers are small and of a yellow colour.

In the third, the flowers are without any female florets: it is herbaceous, and has the leaves cut into very fine segments. It is a native of Tuscany, flowering in June.

The fourth species is a palm in height: the stem villose, leafy: the leaves, like those of chamomile, pubescent: the peduncles terminating, longer than the leaves, when fruiting stiffish: the flowers are of a sulphur colour. It is a native of Spain, Italy, and Siberia.

Culture.—These plants may be raised from slips or cuttings, which should be planted out in a border of good light fresh earth in the spring season, water and shade being afforded till they have stricken root, being afterwards kept clean from weeds till the beginning of autumn, when they should be taken up with care, and planted out where they are designed to remain: when the business of removing them cannot be performed at the above period, it should be delayed till the spring following, as when removed late they are apt to be destroyed in the winter: they succeed best in a poor dry soil.

They have a very ornamental effect in the borders and clumps, when kept properly trimmed in and tastefully intermixed with other similar plants, in the fronts and more conspicuous parts.

SAPINDUS, a genus containing plants of the tree, shrubby, and tender exotic kinds.

It belongs to the class and order *Ocandria Trigynia*, and ranks in the natural order of *Trilatae*.

The characters are: that the calyx is a four-leaved perianth, spreading; leaflets subovate, almost equal, flat, spreading, coloured, deciduous; two of them exterior: the corolla has four ovate, clawed petals; two of them more approximating: nectary of four oblong concave erect leaflets, inserted into the base of the petals: glands four, roundish, inserted also into the base of the petals: the stamina have eight filaments, length of the flower; anthers cordate, erect: the pistillum is a triangular germ: styles three, short: stigmas simple, obtuse: the pericarpium has three capsules, fleshy, globular, connate, inflated: the seed is a globular nut (two-celled).

The species are: 1. *S. Saponaria*, Common Soap-berry Tree; 2. *S. rigidus*, Ash-leaved Soap-berry Tree.

There are other species that may be cultivated for variety.

The first rises with a woody stalk in its native situation, from twenty to thirty feet high, sending out many branches towards the top, which are garnished with winged leaves, composed of three, four, or five pair of spear-shaped leaflets, which are from three to four inches long, and an inch and a quarter broad in the middle, drawing to a point at both ends: the midrib has a membranaceous or leafy border running on each side from one pair of leaflets to the other, which is broadest in the middle between the leaflets; they are of a pale green colour, and are pretty stiff; the flowers are produced in loose spikes at the end of the branches; are small and white, making no great appearance: these are succeeded by oval berries as large as middling cherries, sometimes single, at others two, three, or four are joined together; these have a saponaceous skin or cover, which incloses a very smooth roundish nut of the same form and of a shining black when ripe. It is a native of the West Indies.

The nuts were formerly brought hither for buttons to waistcoats, some tipped with silver, and others with different metals, and were very durable, as they did not wear, and seldom broke.

The second species, according to Miller, has a strong woody stalk which rises about twenty feet high, sending out many short strong branches, covered with a smooth gray bark: the leaves composed of two pairs of spear-shaped leaflets, very stiff and smooth; the inner pair small, seldom more than an inch and half long; the two outer near three inches long, and almost an inch broad in the middle, drawing to points at both ends; they are oblique to the footstalk, of a pale green, and sit close to the midrib: the ends of the branches are divided into two or three footstalks, each sustaining a loose spike of flowers: the berries roundish; generally two, three, or four joined together. It is a native of the West Indies.

Culture.—These plants may be raised from seeds, procured from their native situations, which should be sown in small pots filled with rich fresh earth early in the spring, plunging them in a hot-bed of bark, and watering them frequently:—when the plants appear, the glasses should be raised daily to admit fresh air, and when they have had some growth, they should be shaken out of the pots, carefully separated, and planted in distinct pots filled with light rich mould, re-plunging them in the hot-bed, and shading them from the sun till they have stricken root, when they should have free air admitted daily when the weather is warm, and be frequently watered: as they soon fill the pots with their roots, they should be often removed into larger ones, and be gradually inured to the open air, as when too much forced in the summer they are apt to die in the winter. In the beginning of the autumn they should be removed into the bark-bed of the stove, or be placed upon the shelves of it, where they often succeed better, being managed as other stove plants of the same nature.

They afford variety in stove collections.

SAPONARIA, a genus containing plants of the herbaceous perennial and annual kinds.

It belongs to the class and order *Decandria Digynia*, and ranks in the natural order of *Caryophyllei*.

The characters are: that the calyx is a one-leaved, naked, tubular, five-toothed permanent perianth: the corolla has five petals; claws narrow, angular, length of the calyx; border flat, with the plates wider outwards, blunt: the stamina have ten awl-shaped filaments, length of the tube of the corolla, alternately inserted into the claws of the petals, five later; anthers oblong, blunt, incumbent: the pistillum is a subcylindrical germ: styles two, straight, parallel, length of the stamens; stigmas acute: the peri-

carpium is a capsule, length of the calyx, covered, one-celled, oblong: the seeds numerous, small: the receptacle free.

The species cultivated is *S. officinalis*, Common-Soapwort.

It has a perennial root, striking deep and spreading wide, and creeping by runners: the stems a foot and half in height, upright, round, rigid, jointed, smooth, often reddish, paniced at top: the leaves opposite, connate, quite entire, three-nerved, smooth: the panicle hemispherical, many-flowered, bracteolate: the corolla flesh-coloured or rose-coloured, varying to white, smelling sweet: the petals entire, crowned at the throat: the seeds blackish, with a granulated surface. It is a native of the Southern parts of Europe, flowering from July to September.

There are two varieties: as with double flowers, which is preserved in gardens, but has the same fault with the single one, of spreading very much at the root.

The hollow-leaved, in which the roots do not spread like those of the common sort: the stalks are shorter, thicker, and do not grow so erect; they rise a foot or more in height; the joints are very near and swelling: the leaves are produced singly on the lower part of the stalks, but towards the top they are often placed by pairs; they are about three inches long and two broad, having several longitudinal veins or plaits, and are hollowed like a ladle: the flowers are disposed loosely on the top of the stalk, have large cylindrical calyxes, only one petal, and scarcely any visible stamens; they are of a purple colour, and appear in July.

Culture.—These plants are readily increased by parting the roots, and planting them out either in the autumn or early spring: the hollow-leaved variety may likewise be raised from slips or cuttings planted at the same seasons. It should have a dry situation, where the air is good.

The double sort affords variety in the borders and other parts, and the hollow-leaved variety is useful for ornamenting rock-work.

SARRACENIA, a genus containing plants of the herbaceous perennial kind.

It belongs to the class and order *Polyandria Monogynia*, and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is a double perianth; lower three-leaved: leaflets ovate, very small, deciduous; upper five-leaved; leaflets subovate, very large, coloured, deciduous: the corolla has five ovate petals, bent in, covering the stamens: claws ovate-oblong, straight: the stamina have numerous small filaments: anthers simple: the pistillum is a roundish germ: style

cylindrical, very short: stigma clypeate, peltate, five-cornered, covering the stamens, permanent: the pericarpium is a roundish five-celled capsule: the seeds numerous, roundish, acuminate, small.

The species are: 1. *S. flava*, Yellow Side-saddle Flower; 2. *S. purpurea*, Purple Side-saddle Flower.

The first has the leaves near three feet high, small at the bottom, but widening gradually to the top; they are hollow, and arched over at the mouth like a friar's cowl: the flowers grow on naked pedicels, rising from the root to the height of three feet, and are of a green colour. It is a native of Carolina, Virginia, &c. flowering in June and July.

The second species has a strong fibrous root, which strikes deep into the soft earth, from which arise five, six, or seven leaves, in proportion to the strength of the plant; these are about five or six inches long, hollow like a pitcher, narrow at their base, but swell out large at the top; their outer sides are rounded, but on their inner side they are a little compressed, and have a broad leafy border running longitudinally the whole length of the tube; and to the rounded part of the leaf there is on the top a large appendage or ear standing erect, of a brownish colour; this surrounds the outside of the leaves about two thirds of the top, it is eared at both ends, and waved round the border: from the centre of the root, between the leaves, arises a strong, round, naked footstalk, about a foot high, sustaining one nodding flower at the top: the leaflets of the upper calyx are obtuse, and bent over the corolla, so as to cover the inside of it; they are of a purple colour on the outside, but green within, only having purple edges: the petals are of a purple colour, and hollowed like a spoon. It is a native of most parts of North America, in boggy situations.

Culture.—As these plants grow naturally in soft boggy situations, they are raised with difficulty here. The best mode is to procure them from the places of their natural growth, and to have them taken up with large balls of earth to their roots, and planted in tubs of earth; they should be constantly watered during their passage, otherwise they decay before they arrive: as there is little probability of raising these plants from seeds, so as to produce flowers in many years, if the seeds should even grow, young plants should be taken up for this purpose, as they are more likely to stand than those which have flowered two or three times. When the plants are brought over, they should be planted into pretty large pots, which should be filled with soft spongy earth, mixed with rotten wood, moss, and turf, which is very like the natural

soil in which they grow. These pots should be put into tubs or large pans which will hold water, with which they must be constantly supplied, and placed in a shady situation in summer; but in winter be covered with moss, or sheltered under a frame, otherwise they will not live in this climate; having free air admitted in mild open weather.

SASSAFRAS. See **LAURUS**.

SATTIN, WHITE. See **LUNARIA**.

SATUREIA, a genus containing plants of the low under-shrubby and herbaceous perennial and annual kinds.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatæ*.

The characters are: that the calyx is a one-leaved perianth, tubular, striated, erect, permanent: mouth five-toothed, almost equal, erect: the corolla one-petalled, ringent: tube cylindrical, shorter than the calyx: throat simple: upper lip erect, blunt, acutely emarginate, length of the lower lip: lower lip three-parted, spreading; segments blunt, equal, the middle one a little larger: the stamina have four filaments, setaceous, distant, scarcely the length of the upper lip; the two lower a little shorter: anthers converging: the pistillum is a four-cleft germ: style setaceous, length of the corolla: stigmas two, setaceous: there is no pericarpium: calyx converging, containing the seeds in the bottom: the seeds four, roundish.

The species cultivated are: 1. *S. montana*, Winter Savory; 2. *S. hortensis*, Summer Savory; 3. *S. juliana*, Linear-leaved Savory; 4. *S. Thymbra*, Whorled Savory; 5. *S. capitata*, Ciliated Savory.

The first is a perennial plant, with a shrubby low branching stalk: the branches rise about a foot high, are woody, and have two very narrow stiff leaves, about an inch long, opposite at each joint: from the base of these come out a few small leaves in clusters: the flowers axillary upon short footstalks, shaped like those of the second sort, but larger and paler. They appear in June, and the seeds ripen in autumn. It is a native of the South of France and Italy.

The second species is an annual plant, with slender erect stalks about a foot high, sending out branches at each joint by pairs: the leaves opposite, about an inch long, and one eighth of an inch broad in the middle, stiff, a little hairy, and having an aromatic odour if rubbed: the flowers towards the upper part of the branches axillary; each peduncle sustaining two flowers: the corolla pale flesh-colour. It is a native of the South of France and Italy, flowering from June to August.

The third has very slender woody stalks, which grow erect, about nine inches high, sending out two or three slender side branches towards the bottom: the leaves opposite, stiff: the flowers in whorls for more than half the length of the stalk, seeming as if they were bundled together: the corolla small and white: the whole plant has a pleasant aromatic smell. It is a native of Italy, flowering from May to September.

The fourth species rises about two feet high with a woody stem, and divides into many branches, so as to form a small bush: the leaves somewhat like those of Common Savory, having a strong aromatic scent when bruised.

In this the whorls are four or five, whereas in the preceding there are nineteen or twenty. It is a native of the island of Candia.

The fifth has a low shrubby stalk, which sends branches on every side, about six inches long, and hoary: the leaves stiff, narrow, acute-pointed: the flowers in short roundish spikes at the end of the branches, small and white: the whole plant is hoary and very aromatic. It never produces seeds in this climate. It is a native of the Levant, flowering from June to October.

Culture.—The first sort may be raised from seeds, or by planting slips.

The seeds should be sown in the early spring, as the end of March or beginning of April, on a bed of light rich earth, raking it in lightly; when the plants appear they should be occasionally watered, and kept properly thinned.

Some of these plants, when a few inches high, are often taken up, and planted out in nursery rows six inches apart in moist weather, to remain to the autumn or spring, and then planted out with balls of earth about their roots, in rows a foot asunder, to remain.

But the better method is by planting slips or cuttings at the above period, which readily take root, and form good plants, which in the autumn may be planted out with balls to their roots, in beds or rows a foot apart,

The second sort is raised from seeds, which should be sown thinly in the beginning of April upon a bed of light earth, where the plants are to remain.

Some, however, transplant them in the same manner as the above.

The plants should afterwards be kept clean from weeds, and managed in the same manner as has been directed for Marjoram.

The other tender sorts may be increased by slips or cuttings of the most strong side-shoots, planting them out in pots, (or in a shady border protected by mats) the pots being plunged in a moderate hot-bed: they soon begin to grow, and should have free air and water: when well

rooted in the autumn, they should be removed into separate small pots, filled with fresh undunged mould, and placed in the shade till well rooted, and afterwards in a sheltered situation till the autumn, when they should be taken under a garden frame, having free air when the season is fine, but be well protected from frost.

As these plants seldom continue more than a few years, some should be frequently raised as a supply against they decline.

The two first sorts are useful pot-herbs, and the other kinds afford variety among collections of green-house plants.

SATYRIUM, a genus containing plants of the bulbous-rooted, hardy-flowering perennial kind.

It belongs to the class and order *Gynandria Diandria*, and ranks in the natural order of *Orchideæ*.

The characters are: that the calyx is, as the spathes, wandering: spadix simple: the perianth none: the corolla has five ovate-oblong petals: three exterior; two interior converging upwards into a helmet: nectary one-leafed, annexed to the receptacle by its lower side between the division of the petals; upper lip erect, very short; lower flat, pendulous, prominent behind at the base in a scrotiform bag: the stamina have two filaments, very slender and very short, placed on the pistil: anthers obovate, covered by the two-celled fold of the upper lip of the nectary: the pistillum is an oblong germ, twisted, inferior: style fastened to the upper lip of the nectary, very short: stigma compressed, obtuse: the pericarpium is an oblong capsule, one-celled, three-keeled, three-valved, opening in three parts under the keels, cohering at the top and bottom: the seeds numerous, very small, irregular like saw-dust.

The species are: 1. *S. hircinum*, Lizard Satyrion, or Lizard-flower; 2. *S. viride*, Frog Satyrion; 3. *S. albidum*, White Satyrion.

The first frequently attains the height of three feet, and produces from twenty to sixty or more flowers, remarkable for their fetid goat-like smell: the upper part of the lip is downy, and marked with elegant purple spots on a white ground; otherwise the flowers are more singular than beautiful: the leaves are near five inches long and half an inch broad; the spike of flowers is six inches in length: the corolla of a dirty white, with some linear stripes and spots of a brown colour; the middle segment of the lip of the nectary is two inches long. It is a native of Germany, &c.

It is often called Goat Orchis: "It has been occasionally met with in the neighbourhood about Dartford; but the greediness of the collectors has frequently endangered its total de-

struction, and in some seasons none can be found in flower."

"The circumstance of its varying in size and the breadth of the leaves, has given occasion to old authors to make two species of it: the flowers are sometimes quite white."

2. "It was found at the Cape of Good Hope, on the top of the Table mountain; whence its trivial name."

3. "It is large and panicled: found at the Cape."

4. "This is a fathom in height, with large orange coloured flowers."

5. "In this the lip is muricate with white and purple prickles. Both these were also found at the Cape."

The second species has a stem from five to eleven inches high, and solid, with unequal sharp angles, formed from the edges of the leaves and bractes: the spike lanceolate, from one to three inches long, loose with few flowers: the bractes subulate-lanceolate, keeled, somewhat bowed-in. It is a native of many parts of Europe, flowering from May to August.

The third has the stem from nine to fifteen inches high: the lower leaves oval, sheathing the stem; upper lanceolate, acute: the flowers very numerous, in a long (an inch and half, cylindrical,) close spike: the bractes lanceolate, very acute, longer than the germ: the petals white, oval-lanceolate, all converging: lip of the nectary short, green, divided into three acute segments, the middle one longest and more blunt, the spur blunt, about half as long as the germ. It is a native of Scania, Denmark, &c. flowering in June and July.

Culture.—These plants are not raised without some difficulty: the best mode of increasing them is by taking up the roots with a good ball about them from their natural situations, and planting them in a soil as similar as possible, where they are to grow, letting the ground around them afterwards remain wholly undisturbed.

They sometimes also succeed by seed and offsets from the roots planted out after the stems decay.

They afford variety in borders among other similar plants.

SAVIN. See *JUNIPERUS*.

SAVORY. See *SATUREIA*.

SAVOY CABBAGE. See *BRASSICA*.

SAXIFRAGA, a genus containing plants of the low hardy herbaceous perennial kind.

It belongs to the class and order *Decandria Digynia*, and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is a one-

leafed perianth, five-parted, short, acute, permanent: the corolla has five petals, spreading, narrow at the base: the stamina have ten awl-shaped filaments: anthers roundish: the pistillum is a roundish acuminate germ, ending in two short styles: stigmas blunt: the pericarpium is a subovate two-beaked capsule, two-celled, opening between the points: the seeds numerous, minute.

The species mostly cultivated are: 1. *S. Cotyledon*, Pyramidal Saxifrage; 2. *S. granulata*, White Saxifrage; 3. *S. crassifolia*, Thick-leaved Saxifrage; 4. *S. umbrosa*, London Pride; 5. *S. hypnoides*, Mossy Saxifrage, or Ladies' Cushion; 6. *S. sarmentosa*, China Saxifrage; 7. *S. rotundifolia*, Round-leaved Saxifrage.

There are other species that may be cultivated.

The first has the panicle very much branched, many-flowered, or branched a little with few flowers: the petals unspotted or spotted; and according to Miller, who has made three species of it, the roots are perennial and fibrous, and the leaves are gathered into circular heads, embracing each other at the base like the common Houseleek, in some of the sorts tongue-shaped, about two inches long, and a quarter of an inch broad: the stem about a foot high, purplish, a little hairy, and sending out several horizontal branches the whole length: the flowers are in small clusters at the end of the branches; white with several red spots on the inside. But in others the leaves are smaller. It is a native of the Alps.

It is observed, that when these plants are strong they produce very large pyramids of flowers, which make a fine appearance; and being kept in the shade, and screened from wind and rain, continue in beauty a considerable time: they flower in June. There are several varieties.

The second species has the root composed of several little grains or knobs, attached to one main fibre, and throwing out small fibres from their base: the stem is erect, round, pubescent, leafy, somewhat viscid, branched and panicked at top, of a brown or reddish hue, with which colour the leaves, &c. are also tinged, giving the whole herb a rich glowing appearance; these parts are also clothed with the same kind of hairs, especially the calyx, which is very clammy to the touch: the leaves are somewhat fleshy, lobed, and cut; those next the root on long foot-stalks; those on the stem alternate, subsessile. It is a native of Europe, flowering in May.

It varies with double flowers, in which state it is cultivated as an ornamental plant.

The third has the root superficial, black,

scaly, with the relics of dead leaves, the thickness of a finger or thumb, round, sending down filiform fibres from the lower surface: the stems from the axils of the leaves of the year preceding at the tops of the roots alternate, very short, almost upright, covered with the sheaths of the leaves, quite simple, but branched in autumn: the leaves three or four, alternate, spreading very much, obovate-oblong, crenulate, subretuse, very smooth, veined, a span long, flat, coriaceous: the petioles shorter by half than the leaves, roundish, channelled, smooth, with a wide membrane at the base, of an ovate form, embracing, and in the winter season serving for a gem: the scape or peduncle terminating, solitary, erect, a span high, the thickness of the little finger, roundish, very smooth, purplish, almost naked, many-flowered: the panicle contracted, naked, blood-red, composed of pedate racemes: the flowers inferior, drooping, pedicelled: the pedicels short, round, rugged.

It is observed, that "the stem changes every year into root; that which flowers one year losing its leaves during the winter, turning to the ground, becoming black, and putting forth fibres:" and after the plant has flowered, the stem puts forth branches from the axils of the leaves, which have the panicle of flowers for the next year included in their gems.

According to Curtis, the leaves are large, red on the under, and of a fine shining green on their upper surface, and may be ranked among the more handsome kinds of foliage: the flowering stems, according to the richness and moisture of the soil in which they are planted, rise from one to two or even three feet high; at top supporting a large bunch of purple pendulous flowers, expanding in April and May, and, if the season prove favourable, making a fine appearance. It is a native of Siberia.

It is remarked, that "there is another Saxifrage in gardens, exceedingly like this in appearance, but differing, in producing larger bunches of flowers, and in having larger, rounder, and more heart-shaped leaves."

The fourth species has the leaves all radical, aggregate in tufts, spreading, running down into the petiole, even and quite smooth, often purple beneath: the scape a span high, erect, red, hairy, many-flowered, with a few small alternate bractes: the flowers upright: the calyx finally reflexed: the petals obovate-lanceolate, white or flesh-coloured, most beautifully dotted with yellow and dark red: the germ altogether superior, rose-coloured: the capsule ventricose, tipped with purple. It is a native of Ireland and England, flowering in June and July. It has the names of None-so-pretty, and London Pride.

Painted by J. Edwards

London Published 1841 by G. Kearley Fleet Street

Engraved by F. Langton

Scabiosa atropurpurea
Sweet Scabious

Scilla campanulata
Bell-flowered Squill

The fifth has long slender fibrous roots, throwing out many procumbent leafy shoots, which grow matted together, forming thick tufts: from the common origin of these arises a solitary erect round stem, bearing two or three straggling linear undivided leaves, and terminating in an upright panicle of a few large white flowers: the leaves are alternate, linear, acute, pale green, smooth, their edges only often hairy with soft white woolly threads: the leaves on the shoots simple and undivided; those at the bottom of the stem all deeply three-cleft, with the segments divaricate. According to Withering, the stem, fruitstalks, and calyx are thickly set with short hairs terminated by red globules, and the rest of the plant thinly set with fine white hairs. It is a native of Britain, flowering in May, and often again sparingly in July and August.

The sixth species has the root-leaves petioled, cordate-suborbicular, hairy, crenate, with blunt lobules, oleraceous, having white veins on the upper surface, beneath liver-coloured: the petioles roundish, longer than the leaf: the stem herbaceous, round, a foot and half high, almost leafless, pubescent, as the whole herb is, with hairs standing out; the whole raceme compound, the partial racemes drooping at the end before they flower. Branched runners proceed in abundance from the axils of the root-leaves, terminating in rooting off-sets: three of the petals are smaller, whitish stained with red; two larger, white. It is observed, that "its round variegated leaves, and strawberry-like runners, with the uncommon magnitude of the two lower pendent petals, joined to the very conspicuous glandular nectary, in the centre of the flower, half surrounding the germ, render it strikingly distinct." It is a native of China and Japan, flowering in June and July.

The seventh has the lower leaves almost round, on long footstalks, deeply divided, hairy and green above, pale beneath: the stems erect, about a foot high, channelled and hairy, with kidney-shaped leaves: the stem puts out a few slender footstalks from the upper part, which, together with the stem itself, are terminated by small clusters of flowers, white spotted with red. It is a beautiful plant, and a native of Switzerland, &c.

Culture.—The first sort may be readily increased by planting off-sets taken from the sides of the old plants in small pots filled with fresh light earth, placing them in the shade during the summer, but letting them be exposed to the influence of the sun in winter: all the off-sets should be taken off, as by that means they will flower much stronger: the young plants afford flowers the second year.

The second sort may likewise be increased in the same way, which should be planted out where they are to remain in July, when the stems decay, in fresh undunged earth, giving them a shady situation till winter: they should be set out in large tufts, and when in the open ground have a shady place assigned them.

The third sort may be increased with little trouble by parting the roots, and planting them out in the spring or autumn in the open ground, or in pots in the former situation, being protected in severe weather, and in the latter removed to the green-house or a garden frame.

The fourth may also be raised by offsets in the same way, a shady situation being chosen.

The fifth sort is easily increased by planting its trailing rooted branches in the autumn where they are to remain: it should have a moist soil and shaded situation.

The sixth may be readily raised by the runners, which may be planted in pots to be placed in the green-house, though it will bear the open air in mild winters in a warm sheltered situation.

The last may be increased by parting the roots and planting them out in the early autumn: it should have a moist shady situation, with a rather stiff loamy soil.

They all afford ornament and variety in the clumps, borders, and other parts of pleasure-grounds; except the sixth, which must have a place in the green-house collection.

SCABIOSA, a genus containing plants of the herbaceous, annual, biennial, perennial, and shrubby kinds.

It belongs to the class and order *Tetrandria Monogynia*, and ranks in the natural order of *Aggregatie*.

The characters are: that the calyx is a common perianth, many-flowered, spreading, many-leaved: leaflets in various rows surrounding the receptacle and placed upon it, the inner ones gradually less: proper perianth double, both superior; outer shorter, membranaceous, plaited, permanent; inner five-parted, with the segments subulate-capillaceous: the corolla universal equal, often from unequal ones: proper one-petalled, tubular, four- or five-cleft, equal or unequal: the stamina have four filaments, subulate-capillary, weak: anthers oblong, incumbent: the pistillum is an inferior germ, involved in its proper sheath as in a calycle: style filiform, length of the corolla: stigma obtuse, obliquely emarginate: there is no pericarpium: the seeds solitary, ovate-oblong, involute, crowned variously with proper calyxes: the receptacles common convex, chaffy, or naked.

The species mostly cultivated are: 1. *S. al-*

pina, Alpine Scabious; 2. *S. leucantha*, Snowy Scabious; 3. *S. succisa*, Devil's-bit Scabious; 4. *S. integrifolia*, Red-flowered Annual Scabious; 5. *S. tatarica*, Giant Scabious; 6. *S. gramuntia*, Cut-leaved Scabious; 7. *S. stellata*, Starry Scabious; 8. *S. atropurpurea*, Sweet Scabious; 9. *S. argentea*, Silvery Scabious; 10. *S. graminifolia*, Grass-leaved Scabious; 11. *S. Africana*, African Scabious; 12. *S. Cretica*, Cretan Scabious.

The first has a perennial root, composed of many strong fibres which run deep in the ground: the stems several, strong, channelled, upwards of four feet high: the leaflets four or five pairs, unequal in size and irregularly placed, ending in acute points: the flowers are on naked peduncles at the ends of the branches, of a whitish yellow colour, appearing at the end of June. It is a native of the Alps of Switzerland, &c.

The second species has a perennial root: the lower leaves almost entire, serrate: stem stiff, two feet high, bifid at top, spreading; in the division arises a naked peduncle, which, as also the divisions, are each terminated by a single flower, composed of many white florets. It is a native of the South of France, &c.

The third has also a perennial, oblong, blackish root, near the thickness of the little finger, often growing obliquely, stumped at the lower end so as to appear as if bitten off, whence its trivial name, and furnished with long whitish fibres: the stem from a foot to eighteen inches in height, upright, branched at top, round, rough with hair, and often of a reddish colour: the branches are lengthened out, and each bears one flower: the root-leaves are ovate, quite entire, blunter than the others; the stem-leaves lanceolate, the lower ones remotely toothed, but the upper ones entire; all dark-green, rather coriaceous, harsh and hairy: the flowers in nearly globular heads. It is a native of Europe, flowering from August to the end of October.

The fourth species has an annual root: the stem is not hispid: the branches patulous: the root-leaves, like those of the Daisy, ovate, bluntish, rugged, more acutely serrate; stem-leaves few; branch-leaves lanceolate, embracing, ciliate at the base, seldom toothed or pinnatifid, very long. It is a native of Germany, flowering from June to August.

The fifth rises with a strong branching stalk four or five feet high, closely armed with stiff prickly hairs; lower hairs spear-shaped, about seven inches long, and near four broad in the middle, deeply cut on the sides; the stem-leaves more entire, some of them sharply serrate; those at the top linear and entire: the

flowers from the sides and at the top of the stalks, white, and each sitting in a bristly calyx: the root is biennial. It is a native of Tarry, &c.

The sixth species has the root-leaves villose, ash-coloured, deeply pinnatifid; with the pinules blunt, distinct, the lower ones linear and entire, the upper gradually wider, blunt, gash-toothed: the stem-leaves bipinnate, with the leaflets linear, narrow, unequal, scarcely pubescent: the stem a foot and half in height: it flowers very late, even in November, and is perennial. It is a native of the South of France, &c.

The seventh is annual, the stems three feet high, hairy: the leaves oblong, deeply notched; the upper ones cut almost to the midrib into fine segments: the flowers on long peduncles: the receptacles are globular: the florets large, spreading open like a star, of a pale purple colour. It is a native of Spain and Barbary, flowering in July and August.

It varies with different jagged leaves, and with red and white flowers.

The eighth species has a fibrous annual biennial root, crowned with a large tuft of oblong leaves, variously jagged and cut on the edges: the stems upright, numerous branched on every side, three feet high or more: the calyx is twelve-leaved, recurved, linear, the length of the corolla: the flower very dark purple, with white anthers: the fruit ovate: the receptacle subulate, with bristle-shaped chaffs. It flowers from June to October: the flowers are very sweet, and there is a great variety in their colour, some being of a purple approaching to black, others of a pale purple, some red and others variegated. It also varies in the leaves, some being finer cut than others: and sometimes from the side of the calyx come out many slender peduncles sustaining small flowers, like the (proliferous or) Hen-and-chicken Daisy.

The ninth is a low perennial plant, with a branching stalk spreading wide on every side; the leaves are of a silvery colour; the flowers are small, pale, and have no scent: the stem has white hairs thinly scattered over it: the root-leaves are somewhat toothed; stem-leaves undivided, and ciliate towards the base. It is a native of the Levant, flowering from June to October.

The tenth species has a perennial root, from which arise three or four stalks, the lower parts of which have linear leaves about four inches long, and the eighth of an inch broad, of a silvery colour, ending in acute points: the upper part of the stalk is naked for six or seven inches in length, and sustains at the top one pale-blue

flower. It is a native of the mountains of Dauphiné, flowering in July.

The eleventh has a weak shrubby stalk, which divides into several branches, and rises about five feet high: the leaves are ovate-lanceolate, three inches long, and an inch and half broad, deeply crenate, of a light green, and a little hairy: the peduncle terminating, sustaining one pale flesh-coloured flower. It is a native of Africa, flowering from July to October: it varies in the leaves. The variety with the leaves finely cut, has, according to Miller, the stalks hairy, and dividing into several branches: the bottom leaves are lanceolate crenate and entire; but those on the upper part of the stalk are bipinnate: the flowers are produced on long naked footstalks from the end of the branches; are of a pale flesh-colour and large, but have no scent.

The twelfth rises with a shrubby stalk three feet high, and divides into several woody knotty branches: the leaves are narrow, silvery, entire, four inches long, and a quarter of an inch broad: the flowers stand upon very long naked peduncles at the end of the branches, and are of a fine blue colour. It is a native of Candia and Sicily. According to Miller, the plant from Candia has shorter and much broader leaves, and not so white as those of the Sicilian; the flowers are not so large, and are of a pale purple colour.

Culture.—All the annual and biennial sorts may be increased by seed, which should be sown in a bed or border of common mould, or in pots to be forwarded in the hot-bed in the early spring months; but the biennial sort is better sown in the latter end of the summer, as about August, as they flower stronger and more fully the following summer. Some may however be sown at both seasons.

When the plants have attained some growth, in the spring-sown sort, they should be pricked out into the places where they are to grow, on beds, to be afterwards removed: and in the autumn-sown sorts into nursery-rows, six or eight inches apart, to be removed into the places where they are to remain, with balls about their roots, in the following spring, being duly watered and kept free from weeds.

The starry sort is best sown in patches in the borders or clumps where the plants are to flower.

The herbaceous perennial kinds may be readily increased by sowing the seeds in a bed or border of good light earth, in the spring season, the plants being planted out when they have attained a little growth where they are to grow: they are also capable of being raised by parting

the roots and planting them out where they are to grow in the autumn.

The shrubby kinds may be readily raised by planting slips or cuttings of the young branches in the spring or summer season, in the former season in pots and plunged in a moderate hot-bed, or under a glass frame; but in the latter, in the open ground, being well shaded and watered. They soon become tolerably well rooted, and in the autumn may be potted off into separate pots filled with light loamy earth, and managed in the same manner as other exotic green-house plants during the winter.

The annual and perennial sorts afford ornament and variety among other plants of the flower kind in the borders, &c., and the shrubby kinds produce variety in green-house collections.

SCALLION. See **ALLIUM.**

SCANDIX, a genus containing plants of the hardy herbaceous annual and perennial kinds.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Umbellatæ* or *Umbelliferae*.

The characters are: that the calyx is an universal umbel, long, with few rays: partial more abundant: involucre universal none: partial five-leaved, length of the umbellet: perianth proper obsolete: the corolla universal difform, radiate: florets of the disk abortive: proper petals five, inflex-emarginate: the inner ones smaller; outmost larger: the stamina have five capillary filaments: anthers roundish: the pistillum is an oblong inferior germ: styles two, awl-shaped, length of the least petal, distant, permanent: stigmas in the radiant florets obtuse: there is no pericarpium: fruit very long awl-shaped, bipartite: the seeds two, awl-shaped, convex and grooved on one side, flat on the other.

The species is *S. cerfolium*, Garden Chervil.

It has an annual root: the leaves are of an exceedingly delicate texture, smooth, shining, tripinnate, with the segments deeply semipinnate, and the lobules lanceolate, shortly two-toothed, or three-toothed: the stem smooth, from a foot to two feet in height, hairy only under the origin of the branches, whence always are produced two branches and a single leaf: the flowers white. It is a native of many parts of Europe, flowering in May. It was formerly much more cultivated than at present. It is used as a culinary plant in winter and spring, and is a native of the Levant.

Culture.—This plant may be raised from seed by sowing at different times in the early spring, as from February to March, and also in August for winter use, in beds of common earth, raking

the seed in : it afterwards only requires to be kept clean from weeds.

The leaves are used in their young state while green and tender.

SCARLET OAK. See QUERCUS.

SCHINUS, a genus affording plants of the shrubby evergreen exotic kinds for the greenhouse and stove.

It belongs to the class and order *Diœcia Decandria*, and ranks in the natural order of *Dumosæ*.

The characters are : that in the male the calyx is a one-leafed, five-parted perianth, spreading, acute : the corolla has five oval petals, spreading, petioled : the stamina have ten filiform filaments, length of the corolla, spreading : anthers roundish : the pistillum a rudiment without a stigma. Female—the calyx is a one-leafed, five-parted perianth, acute, permanent : the corolla has five oblong petals, spreading, petioled : the pistillum is a roundish germ : style none : stigmas three, ovate : the pericarpium is a globular three-celled berry : the seeds solitary, globular.

The species are : 1. *S. molle*, Peruvian Mastick Tree ; 2. *S. Areira*, Brazilian Mastick Tree.

The first rises with a woody stem eight or ten feet high, dividing into many branches, covered with a brown rough bark : the leaves are alternate on the branches, composed of several pairs of leaflets from ten to fifteen, each about an inch and half long, and a quarter of an inch broad at the base, lessening gradually to the point, and having a few serratures on their edges ; they are of a lucid green, and emit a turpentine odour when bruised. The flowers are produced in loose bunches at the end of the branches ; are very small, white, and have no odour. It is a native of Peru.

The second species differs from the first only in having the leaflets entire and all equal in size. It is a native of Brazil and Peru.

Culture.—The first is increased by sowing seeds obtained from its native situation in pots filled with fresh mould, plunging them in a moderate hot-bed ; fresh air and water should be frequently given, when in five or six weeks the

plants will be fit to plant out in separate small pots filled with soft loamy mould, re-plunging them in the hot-bed, and giving proper shade till they are fresh rooted. They should afterwards be gradually inured to the open air during the summer season, being taken under shelter before the frosts commence.

They are tender while young, requiring a little warmth in winter, but the protection of the greenhouse will be sufficient afterwards.

It is also capable of being increased by layers and cuttings ; the former may be laid down in the spring, and the later planted out in the early spring ; the plants when well rooted being treated as the seedlings.

The second sort may be increased in the same method ; but the plants require to be continued in the stove for several winters, when they may be preserved in a moderate greenhouse.

They afford variety among other exotic plants in greenhouse collections.

SCILLA, a genus containing plants of the hardy, bulbous-rooted, perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Coronarieæ*.

The characters are : that there is no calyx : the corolla has six ovate petals, spreading very much, deciduous : the stamina have six awl-shaped filaments, shorter by half than the corolla : anthers oblong, incumbent : the pistillum is a roundish germ : style simple, length of the stamens, deciduous : stigma simple : the pericarpium is a subovate capsule, smooth, three-grooved, three-celled, three-valved : the seeds many, roundish.

The species are : 1. *S. maritima*, Officinal Squill ; 2. *S. Lilio-Hyacinthus*, Lily-rooted Squill ; 3. *S. Italica*, Italian Squill ; 4. *S. Peruviana*, Peruvian Squill ; 5. *S. amœna*, Nodding Squill ; 6. *S. campanulata*, Spanish Squill ; 7. *S. autumnalis*, Autumnal Squill.

The first has a very large root, somewhat pear-shaped, composed of many coats as in the Onion, and having several fibres coming out at the bottom, and striking deep in the ground. From the middle of the root arise several shining leaves, a foot long, and two inches broad at their base, lessening all the way to the top, where they end in points ; they continue green all the winter, and decay in the spring : then the flower-stalk comes out, rising two feet high, naked about half way, and terminated by a pyramidal thyrse of flowers, which are white. It is a native of Spain, Portugal, &c. flowering here in April and May.

There are varieties with a red, and with a white root.

The second species has a scaly root like the Lily; it is oblong and yellow, very like that of Martagon: the leaves are shaped like those of the White Lily, but are smaller: the stalk is slender, and rises a foot high; it is terminated by blue flowers, which appear in June. It is a native of Spain, Portugal, &c.

The third has a roundish solid bulb, like that of the hyacinth: the leaves come out sparsely, and are very like those of the English hare-bells: the stem seven or eight inches high, terminated by clustered flowers of a pale blue colour; at first disposed in a sort of umbel or depressed spike, but afterwards drawing up to a point and forming a conical corymb.

The fourth species has a large solid root, raised a little pyramidal in the middle, covered with a brown coat, from this come out before winter five or seven leaves, six or eight inches long, of a lucid green, keeled, and spreading almost flat on the ground: from the centre of these come out one, two, or three scapes, thick, succulent, six or eight inches high, terminated by a conical corymb of flowers, upon pretty long pedicels.

There are varieties with a deep blue, and with a white flower; it is often known by the name of Hyacinth of Peru. It is a native of Spain, Portugal, and Barbary.

The fifth has a large solid purplish root, from which come out five or six leaves, lying on the ground, above a foot long, and an inch broad, keeled, channelled, and of a lucid green; from among these arise two, three, or four purplish stalks, eight or nine inches high, sustaining towards the top five or six flowers, which come out singly from the side; they are of a violet-blue colour, and appear in April. It is a native of the Levant.

In the sixth species the bulb is oblong, white, whence come out five or six leaves, a foot long, and half an inch broad, of a lucid green, and a little keeled: scape nine or ten inches high, firm, and sustaining many flowers at the top, disposed in a loose panicle, each on a pretty long pedicel which is erect, but the flower itself nods: the corolla is of a deep blue violet colour. It is a native of Spain and Portugal, flowering in May.

The seventh has the bulb ovate-roundish, coated, whitish: the leaves numerous, much shorter than the scape, two or three inches long, linear, obtuse, channelled, spreading, scape from three or four to six inches in height, round, upright, striated, below whitish green, above purplish; appearing villose when magnified. Sometimes there is a second scape: the flowers six, ten, or even twenty in a corymb, which is

soon lengthened out into a raceme. It is a native of France, Spain, &c.

It is observed that "most old writers distinguish a larger and a smaller sort; but these differ merely in size: and some have noticed a variety with white flowers."

Culture.—These plants may be increased by offsets from the roots, and by seeds, but the first is the better mode.

The offsets may be taken off every other year, and be planted out at the time the leaves and stems decay.

The seed should be sown in the autumn, on light mould in shallow boxes or pans, in the same manner as in the Hyacinth, the same circumstances being attended to in the culture. The plants are long in flowering in this way, except in the last species, which should have a dry loamy soil.

The first sort, as being a native of the sea-shores, cannot be well propagated in other situations, as the plants are apt to be destroyed by the frosts in winter, and to grow indifferently in the summer season from the want of salt water.

They afford variety in the beds and borders of pleasure-grounds.

SCORPION SENNA. See CORONILLA.

SCORPIURUS, a genus containing hardy herbaceous plants of the annual kind.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a simple umbel: perianth one-leafed, erect, inflated, very slightly compressed, half-five-cleft, acute: teeth almost equal: the upper ones less divided: the corolla papilionaceous: banner roundish, emarginate, reflexed, spreading: wings sub-ovate, loose, with a blunt appendix: keel half-mooned, with the belly gibbous, acuminate, erect, two-parted below: the stamina have diadelphous filaments, (simple and nine-cleft,) ascending: anthers small: the pistillum is an oblong germ, cylindrical, a little reflexed: style bent-in upwards: stigma a terminating point: the pericarpium is an oblong legume, subcylindrical, coriaceous, striated, rugged, revolute, divided internally into several transverse cells, obscurely knobbed externally by the contraction of the joints: the seeds are solitary, roundish.

The species cultivated are: 1. *S. vermiculata*, Common Caterpillar; 2. *S. muricata*, Two-flowered Caterpillar; 3. *S. sulcata*, Furrowed Caterpillar.

The first has the stalks herbaceous, trailing, above a foot long, lying on the ground, and having at each joint a spatulate leaf on a long footstalk: the peduncles axillary, sustaining at the top one

yellow flower, which is succeeded by a thick twisted pod, the size and appearance of a large green caterpillar. It is a native of the South of Europe.

The second species has stronger stalks than the first; the leaves are much broader; the peduncles support two smaller flowers; the pods are slender, longer and more twisted, and are armed with blunt spines on their outside. It is a native of the South of Europe.

The third has slenderer stalks than either of the former; the leaves stand upon shorter foot-stalks, but are shaped like those of the first sort; the peduncles are slender, and frequently support three flowers; the pods are slender, not so much twisted as the former, and armed on their outside with sharp distinct spines. It is a native of the South of Europe, and Barbary.

Culture.—These plants may be increased by sowing the seeds in the places where they are to remain in the early spring months, three or four seeds being put in, in a place, the plants should be thinned properly and kept clean from weeds afterwards, when they will produce flowers, and pods having the resemblance of caterpillars, about the month of June.

The first sort is the most deserving of cultivation, as being the largest in the pods and most perfectly formed.

They afford ornament and variety in their curious pods.

SCORZONERA, a genus containing a plant of the tap-rooted esculent kind.

It belongs to the class and order *Syngenesia Polygamia Æqualis*, and ranks in the natural order of *Compositæ Semiflosculosæ*.

The characters are: that the calyx is common, imbricate, long, subcylindrical: scales about fifteen, scariosc at the edge: the corolla compound, imbricate, reniform: corollæ hermaphrodite numerous, the outer a little longer: proper one-petalled, ligulate, linear, truncate, five-toothed: the stamens have five capillary filaments, very short: anther cylindrical, tubular: the pistillum is an oblong germ: style filiform, length of the stamens: stigmas two, reflexed: there is no pericarpium: calyx ovate-oblong, converging and finally spreading and reflexed: the seeds solitary, oblong, cylindrical, striated, shorter by half than the calyx: pappus feathered, sessile, with chaffy and bristly rays mixed: the receptacle naked.

The species cultivated is *S. Hispanica*, Garden Viper's-grass, or Spanish Scorzonera.

It has a carrot-shaped root, about the thickness of a finger, and covered with a dark brown skin; it is white within, and has a milky juice: the lower leaves nine or ten inches long, and an

inch and half broad in the middle, ending with a long acute point: the stalk three feet high, smooth, branching at top, and having on it a few narrow embracing leaves: the flowers are bright yellow. It is a native of Spain, the South of France, &c.

It is cultivated for the root, which is boiled and eaten as carrots, or it may be tried in batter, which is probably the better way of using it. They are ready for use in the autumn and winter season.

Culture.—These crops should be raised from seed sown either in the autumn or spring season, about April, in an open spot of ground where the soil is light and fine. The best mode of sowing them is in shallow drills, about a foot apart, in a thin manner, covering them in to the depth of half an inch: the plants, when of some growth, should be thinned out when they are too thick, to the distance of six or eight inches, keeping them clean from weeds by hoeing.

Some also raise them by sowing the seed broadcast over the surface, and afterwards thinning the plants or transplanting them into other beds; but the first is the most successful method, and transplanting should never be practised with tap-rooted plants.

The roots may be taken up in the autumn, and preserved in the same manner as those of carrots; but they are sometimes left in the ground to be pulled as they are made use of.

In order to save seed, some of the best plants should be left where sown, to run to seed, which, when perfectly ripened, should be collected and preserved in a dry situation till wanted.

SCOTCH FIR. See **PINUS**.

SCREW-PINE. See **PANDANUS**.

SCREW-TREE. See **HELICTERES**.

SCROPHULARIA, a genus comprising plants of the fibrous-rooted, herbaceous, and shrubby kinds.

It belongs to the class and order *Didynamia Angiospermia*, and ranks in the natural order of *Personatæ*.

The characters are: that the calyx is a one-leaved perianth, five-cleft, permanent: segments shorter than the corolla, rounded: the corolla one-petalled, unequal: tube globular, larger, inflated: border five-parted, very small: segments, the two upper larger, erect; two lateral, spreading a little; one lowest, bent back: the stamens have four linear filaments, declining, length of the corolla; of which two are later: anthers twin: the pistillum is an ovate germ: style simple, situation and length of the stamens: stigma simple: the pericarpium is a roundish capsule, acuminate, two-celled, two-valved: partition folded, constructed of the margins of

the valves bent in; opening at the top: the seeds very many, small: the receptacle roundish, insinuating itself into each cell.

The species cultivated are: 1. *S. frutescens*, Shrubby Figwort; 2. *S. trifoliata*, Three-leaved Figwort; 3. *S. sambucifolia*, Elder-leaved Figwort; 4. *S. lucida*, Shining-leaved Figwort.

The first has the stem perennial, (or becoming woody,) four-cornered, acute-angled, brachiate below: the leaves ovate, toothed, shining, smooth, small, opposite: the lower obovate; the upper oblong: the raceme terminating, leafy, with quite entire bracts, and opposite trifid peduncles, the length of the bracts: corollas small, very dark purple, with the lateral segments white, and the lowest very small. A native of Portugal.

The second species has the stem simple or sparingly branched, erect, smooth, four-cornered, striated: the leaves cordate, smooth and even, shining, veined, obtuse, unequally and obtusely double-toothed, petioled; the lower ones often eared at the base: the raceme interrupted: the peduncles alternate: the flowers pedicelled, in racemelets. According to Plukenet, they are beautifully variegated with red and yellow. It is a native of Corsica and Africa, and is biennial or perennial.

In the third the stem is erect, four-cornered from the decurrent petioles: the leaves pinnate, with five or seven leaflets, (besides the smaller ones placed between them) cordate, wrinkled, smooth above, serrate, with the end one larger: the raceme terminating, composed of very short, subdichotomous, axillary peduncles in pairs: flowers large, purple with the lower lip greenish. It is a native of Portugal, flowering from July to September, and perennial.

The fourth species, according to Miller, is a biennial plant, with stalks fifteen inches high, thick, smooth, and having scarcely any corners: leaves pinnate, narrow, of a lucid green, thick, succulent, and divided into many leaflets, which are again divided (bipinnate): flowers in loose bunches on the sides and at the top of the stalk, of a dark brown colour with a mixture of green. It is a native of the kingdom of Naples.

Culture.—These plants may be increased by seeds, which should be sown in autumn in the borders or other places where the plants are to remain. The plants should be kept free from weeds; when the roots continue several years, unless destroyed by severe frosts. It is therefore a good practice to have some in pots protected by a frame and glasses: and as the young plants flower the strongest, a proper succession should be sown annually. They may also be sometimes raised from the parted roots; and the shrubby sorts by cuttings in the summer.

They afford ornament in the clumps, &c.

VOL. II.

SCULL-CAP. See SCUTELLARIA.

SCUTELLARIA, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Ferticillatæ*.

The characters are: that the calyx is a one-leaved perianth, very short, tubular: mouth almost entire; after flowering closed with a lid: the corolla one-petalled, ringent: tube very short, bent backwards: throat long, compressed: upper lip concave, trifid; middle little segment concave, emarginate; side ones flat, sharpish, lying under the middle one; lower lip wider, emarginate: the stamens have four filaments, concealed beneath the upper lip, of which two are longer: anthers small: the pistillum is a four-parted germ: style filiform, situation and length of the stamens: stigma simple, curved in, acuminate: there is no pericarpium: calyx closed by a lid, helmet-shaped, doing the office of a capsule, three-sided, opening by the lower margin: the seeds four, roundish.

The species are: 1. *S. integrifolia*, Entire-leaved Skull-cap; 2. *S. peregrina*, Florentine Skull-cap; 3. *S. altissima*, Tall Skull-cap.

The first has the stems two feet high, sending out many side branches: the lower leaves heart-shaped and serrate, standing upon pretty long foot-stalks; upper leaves ovate and entire: the flowers in very long loose spikes at the end of the branches; they are of a purple colour, and appear at the end of June. It is a native of North America.

The second species has the stem hairy, two feet high: the flowers are purple or white. It is a native of Italy, &c.

The third has the stems three or four feet high, sending out a few slender branches: the flowers are purple, with longer tubes than those of any of the other sorts. It is a native of the Levant.

Culture.—These are all raised from seed, which should be sown in the autumn or spring, but the former is the better season, in the places where they are to remain, or in a border to be removed afterwards. When the plants are up they should be properly thinned out and kept free from weeds.

They afford variety in the borders, clumps, and other parts of pleasure-grounds.

SEDUM, a genus containing plants of the hardy herbaceous succulent kind.

It belongs to the class and order *Decandria Pentagynia*, and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is a five-cleft perianth, acute, erect, permanent: the corolla has five petals, lanceolate, acuminate, flat, spreading: nectaries five; each a very small emarginate scale, inserted into each germ at the base on the outside: the stamens have ten awl-shaped filaments, length of the corolla: anthers roundish: the pistillum has five oblong germs, ending in more slender styles: stigmas obtuse: the pericarpium five capsules, spreading, acuminate, compressed, emarginate towards the base, opening on the inside longitudinally by a suture: the seeds numerous, very small.

The species cultivated are: 1. *S. Telephium*, Orpine Stonecrop; 2. *S. Anacampteros*, Evergreen Orpine; 3. *S. Aizoon*, Yellow Stonecrop; 4. *S. populifolium*, Poplar-leaved Stonecrop; 5. *S. stellatum*, Starry Stonecrop; 6. *S. Cepaea*, Purslane-leaved Stonecrop; 7. *S. dasycyllum*, Thick-leaved Stonecrop; 8. *S. reflexum*, Yellow Stonecrop; 9. *S. rupestre*, Rock Stonecrop; 10. *S. Hispanicum*, Spanish Stonecrop; 11. *S. album*, White Stonecrop; 12. *S. acre*, Biting Stonecrop, or Wall Pepper; 13. *S. saxangulare*, Insipid Stonecrop; 14. *S. Anglicum*, English or Mild White Stonecrop; 15. *S. annuum*, Annual Stonecrop.

The first has a perennial tuberous root: the stems from one to two feet high and upwards, upright, simple or unbranched, leafy, round, smooth, solid, reddish and often dotted with red: the leaves almost covering the stem, sessile, ovate, fleshy, tooth-serrate, smooth and even, of a blueish green colour: the corymbs terminating, many-flowered, close or heaped together: the flowers deep purple, very rarely white in this climate, though that seems to be the most common colour in some foreign countries. It is a native of Portugal.

There are several varieties, as with purple flowers, with white flowers, with broad leaves, and the Greater Orpine.

The second species has fibrous perennial roots: the stems trailing: the leaves standing alternate round the stems, almost an inch long, and half an inch broad: the flowers in a compact corymb, sitting close on the top of the stem: they are star-shaped, of a purple colour,

and appear in July. It is an evergreen; and a native of Germany.

The third has a perennial root, composed of many thick fleshy fibres, from which come out several stalks rising near a foot high: the leaves are alternate on every side, thick, two inches and a half long, and three quarters of an inch broad, and slightly serrate: the flowers bright yellow. It is a native of Siberia, flowering from July to September.

The fourth species has the leaves cordate, thick and fleshy: the stem herbaceous, branched, erect, patulous, even, a foot high: the leaves alternate, remote, only at the ramifications, blunt, fleshy, smooth. When it grows in an open situation, exposed to the sun, the leaves and stalks become of a bright red colour. It is a native of Siberia, and the only hardy *Sedum* cultivated with us that has a shrubby stalk: the leaves are deciduous. It flowers in July and August, and is proper for a rock plant.

The fifth is a low annual plant: the stalks rise three inches high, dividing at top into two or three parts: the flowers come out singly from the side of the stalk; are white, star-pointed, and succeeded by star-pointed rough capsules. It is a native of Germany, &c.

The sixth species has also an annual root: the stalks six or seven inches high, dividing into smaller branches, which sustain small white flowers growing in large panicles. It is a native of Germany, France, &c.

There is a variety which has the stem more erect, and the lower leaves in threes or fours, the next opposite, and the uppermost alternate.

The seventh has a perennial (biennial) root, composed of small white fibres: the stems numerous, weak, prostrate and creeping, about three inches long or somewhat more, branched, in tufts, round, weak, clammy, leafy: the flowering branches erect: the leaves mostly opposite, closely imbricate, sessile, very thick and fleshy, broader than long, convex on the lower, nearly plane on the upper surface, glaucous often with a tinge of purple; dotted and sometimes having a net of red veins: on the flowering branches they are alternate. It is a native of many parts of Europe, as France, &c.

When introduced into a garden, it propagates itself freely upon walls, in waste places, and about garden pots; and no plant is better adapted to the purpose of decorating rock-work, as it grows without any trouble, in any aspect, multiplying very much by young shoots, and always looks beautiful.

The eighth species has also a perennial root: the stems round, leafy, branched at the base, often hanging down, erect at the top; the leaves scattered, alternate, adnate-sessile, loose at the

Sedum Anacampseros
 1 Evergreen Orpine

Sophora Tetraptera
 2 Winged-Podded Sophora

base and produced, erect above, compressed, acuminate, extremely succulent, smooth, rather glaucous, frequently tinged with red; the lower ones turned back; when old they easily fall off: the flowers are in a terminating subcymed panicle, with many-flowered branches, for the most part recurved; the flowers erect, bright yellow. It is a native of Europe, and is common here on walls and thatched roofs, and rocks in the northern counties, flowering in July.

The ninth is a little smaller than the eighth: the leaves closely imbricate (before flowering) in five or six rows, glaucous, flattened a little, acuminate; on the flowering stem somewhat remote, as in that sort, all erect, not bent back at the point. According to Withering, the disposition of the leaves in five or six rows may be best observed by viewing the plant with the ends of the branches opposed to the eye: the panicle subcymed, many-flowered, with the branchlets scarcely reflexed: the flowers of a bright yellow or gold colour, often six-cleft. It is a native of England and Wales, &c., perennial, flowering in July.

This, as well as the above, is cultivated in Holland and Germany to mix with lettuces in salads.

The tenth has a slender, fibrous, perennial root: the stems several, a hand high, reclining at the base, and then erect, round, tinged with red: the leaves, on the flowering stems, pale green dotted with purple, oblong, thickish, round on one side and flat on the other; towards the top, under the flowers, more swelling and shorter: leaves on young plants or barren shoots, in bundles, glaucous, without any purple dots, thinner, from a narrow base widening gradually, and ending in a blunt point: the stems divide at top into a few branchlets, forming a sort of umbel, (or rather cyme,) bearing sessile, star-like white flowers, stained with pale purple from a purple groove running along the petals: these are six, sometimes seven in number, keeled and cusped. It is a native of Spain and Carinthia, flowering in July.

The eleventh species has a perennial, fibrous root: the stems decumbent at bottom, and there throwing out fibres; flowering stems upright, from three inches to a span in height, round, leafy, branched, smooth: the leaves scattered thinly, spreading out horizontally, sessile, cylindrical, very blunt, smooth, fleshy, somewhat glaucous and generally reddish: panicle terminating, alternately branched, subcymose, many-flowered, smooth. It is a native of Europe, on rocks, walls and roofs, flowering in July.

It is eaten by some as a pickle.

The twelfth has also a perennial, fibrous root: the stems numerous, growing in tufts, much

branched, decumbent, and creeping at the base, then upright, three inches high, smooth, round, very leafy: the leaves closely imbricate, blunt, flattened a little, from upright spreading, loose at the base: the cymes terminating, solitary, few-flowered: the flowers erect, sessile. It is a native of Europe, flowering in July.

The thirteenth species has the habit of the preceding sort, but is somewhat larger: the leaves are subcylindrical; not ovate, and come out mostly by threes in a double row, and hence appear to be imbricate in six rows; this is most obvious in the young shoots: they are very spreading, loose at the base, and scarcely gibbous: the cyme is leafy: the flowers of a golden yellow colour. It is not acrid. It is a native of many parts of Europe, flowering at the end of June.

The fourteenth has an annual, fibrous root: the stems in tufts, decumbent at the base, smooth, red, leafy: the leaves mostly alternate or nearly opposite, bluntish, somewhat glaucous, produced and loose at the base: the cymes terminating, solitary, almost leafless, racemed: the flowers erect, five-cleft. It is a native of Britain and Norway.

The fifteenth species is also an annual plant, with an erect stalk, seldom rising above two or three inches high: the leaves are of a grayish colour: the flowers are small and white, and grow at the top of the stalk, in a reflexed spike. It is a native of the North of Europe.

Culture.—These plants are all raised without much difficulty, by proper care and attention to have the soil dry and of the poor sandy kind.

Culture in the Orpine sorts.—These may all be readily increased by planting cuttings, during the summer months, in light mould in a shady situation, or in pots placed in similar situations. The plants in the open ground, as well as those in pots, should be kept clean from weeds, and be watered frequently when the weather is dry.

They may likewise be raised by parting the roots, and planting them in a similar manner in the spring or autumn. When the plants are once well established, they spread rapidly, and require little or no care.

Culture in the Stonecrop kind.—These are raised without much trouble, by planting out their trailing stalks in the spring or summer season, which readily take root. They thrive most perfectly on old walls, buildings, or rock-works. Where cuttings or roots of the perennial kinds are planted in some soft mud, placed upon such situations, they quickly take root and spread into the different joints and crevices, covering the whole in a very short time.

The seeds of the annual sorts also, when sown

soon after they become ripe in such situations, soon come up and support themselves without further trouble.

Most of the perennial sorts are kept in the nurseries in full plants, fit for setting out in the borders, pots, &c. either in the spring for flowering the same year, or in the autumn to flower in the following year.

These plants may be planted out in any dryish light soil, in borders, beds, and other places, and in the sides of dry banks, or in any elevated rubbishy soil, as well as in pots to move to different parts occasionally; or also some of the evergreen kinds, to introduce in their pots among winter plants under shelter, to increase the variety. In most sorts, they may also be introduced as rock plants, to embellish artificial rock-works, ruins, and other similar places in pleasure-grounds. The Stonecrops and other low trailing kinds may also be made to occupy the tops of any low walls, pent-houses, sheds, or other low buildings.

The twelfth and thirteenth sorts may likewise be disposed in patches towards the fronts of borders, &c. as they spread thick and tufty close to the ground, and flower abundantly; and being planted in pots, are proper to place in the outside of windows, copings of low walls, and in balconies, and court yards, in assemblage with other low fancy plants; they will closely over-spread the surface, and flower profusely as far as they extend.

SELAGO, a genus furnishing plants of the shrubby and under-shrubby kinds.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Aggregateæ*.

The characters are: that the calyx is a one-leaved, four-cleft perianth, (five-cleft,) small, permanent: lower segment larger: the corolla one-petalled: tube very small, filiform, scarcely perforated: border spreading, five-parted, almost equal; the two upper segments smaller; the lowest larger: the stamina have four capillary filaments, length of the corolla, into which they are inserted; the two upper ones longer: anthers simple: the pistillum is a roundish germ: style simple, length of the stamens: stigma simple, acute: there is no pericarpium: corolla (calyx) involving the seed: the seed one or two, roundish.

The species cultivated are: 1. *S. corymbosa*, Fine-leaved Selago; 2. *S. spuria*, Linear-leaved Selago; 3. *S. ovata*, Ovate-headed Selago.

The first has slender woody stems, rising seven or eight feet high, but so weak as to require support; they send out many slender branches: the leaves are short, linear, hairy, coming out in clusters: the flowers small, and

of a pure white; appearing in July and August, but not followed by seeds in this climate.

The second species has a suffruticose stem: the leaves alternate, clustered: the spikes ovate-oblong, blunt, closely imbricate; with oblong, membranaceous bractes: the corollas five-cleft, violet; with a long filiform tube: the capsule six-valved. It is biennial, flowering in June.

The third has white flowers, with a yellow spot on the two uppermost segments, and sometimes on all of them, and an orange spot at the mouth of the tube. It is valuable not so much on account of its beauty, as the curious structure of its spikes, and the fragrance of its flowers. It flowers in June and July, and as well as the rest it is a native of the Cape.

Culture.—They may be increased by cuttings and layers. The cuttings should be made from the young under shoots, and be planted out during the summer months in a bed of fresh earth, covering them close with a bell- or hand-glass, shading them from the sun, and refreshing them now and then with water. They should be gradually hardened, and then transplanted into small pots, placing them in the shade till they have taken root. The layers may be laid down in the autumn or spring, and when well rooted be taken off and planted out in pots, as above. The plants should afterwards be placed out with other hardy greenhouse plants, and about the end of October removed into the dry stove. They only require protection from frost, being treated in the same manner with the hardier sort of greenhouse plants.

They afford ornament and variety in greenhouse collections.

SEMPERVIVUM, a genus containing plants of the succulent, hardy, herbaceous, evergreen, and shrubby perennial kinds.

It belongs to the class and order *Dodecandria Polygynia*, (Dodecagynia,) and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is a six- to twelve-parted perianth, concave, acute, permanent: the corolla has six to twelve petals, oblong, lanceolate, acute, concave, a little bigger than the calyx; the stamina have from six to twelve filaments (or more), subulate-slender: anthers roundish: the pistillum from six to twelve germs, in a ring, erect; ending in as many spreading styles: stigmas acute.

The species cultivated are: 1. *S. tectorum*, Common Houseleek; 2. *S. globiferum*, Globular Houseleek; 3. *S. arachnoideum*, Cobweb Houseleek; 4. *S. montanum*, Mountain Houseleek; 5. *S. arboreum*, Tree Houseleek; 6. *S. Canariense*, Canary Houseleek.

The first has a perennial fibrous root: the root-leaves in form of a full-blown double-rose,

Canna leaved Strelitzia.

sessile, wedge-shaped or obovate, somewhat more than an inch long, very fleshy, thick, flat above, a little convex beneath, keeled and whitish, smooth on both sides, the edges fringed with hairs and generally tinged with red, pointed, upright, gradually smaller inwards: offsets on long footstalks, globular, the size of a pigeon's egg or larger, composed of erect leaves lying over each other: the flowering-stem upright, from nine inches to a foot in height, round, fleshy, pubescent, having alternate, lanceolate, thinner leaves on it, of a reddish colour, at top branched and forming a sort of corymb; the branches spreading and bending back: the flowers numerous, clustered, upright, pubescent, flesh-coloured, all growing one way. It is a native of Europe, flowering in July.

The second species has the leaves much narrower, and the heads furnished with a greater number of them than those of the first sort, which grow more compact, and are closely set on their edges with hairs: the offsets are globular, their leaves turning inward at the top, and lying close over each other; these are thrown off from between the larger heads, and, falling on the ground, take root, whereby it propagates very fast: the flower-stalks are smaller, and do not rise so high as those of the former; and the flowers are of a paler colour. It is a native of Russia, Austria, &c. flowering in June and July.

The third has much shorter and narrower leaves than the first: the heads are small and very compact: the leaves are gray, sharp-pointed, and have slender white threads crossing from one to the other, intersecting each other in various manners, so as in some measure to resemble a spider's web: the flower-stalks about six inches high, succulent and round, having awl-shaped succulent leaves placed on them alternately: the upper part divides into two or three branches, upon each of which is a single row of flowers ranged on one side; each composed of eight lanceolate petals, of a bright red colour, with a deep-red line running along the middle; they spread open in form of a star. It is a native of Switzerland and Italy, flowering in June and July.

The fourth species greatly resembles the first, but the leaves are smaller, and have no indentures on their edges: the offsets spread out from the side of the older heads, and their leaves are more open and expanded: the flower-stalk is nine or ten inches high, having some narrow leaves below; the upper part is divided into three or four branches, closely set with deep-red flowers composed of twelve petals, and twenty-four stamens with purple anthers. It is a native of Germany, &c. flowering in June and July.

The fifth rises with a fleshy smooth stalk eight or ten feet high, dividing into many branches, which are terminated by round heads or clusters of leaves lying over each other like the petals of a double rose, succulent, of a bright green, and having very small indentures on their edges: the stalks are marked with the vestiges of the fallen leaves, and have a light brown bark: the flower-stalks rise from the centre of these heads; and the numerous bright-yellow flowers form a large pyramidal spike, or thyse. It is a native of Portugal, &c. flowers through the winter, commonly from December to March.

The sixth species seldom rises above a foot and a half high, unless the plants are drawn up by tender management: the stalk is thick and rugged, chiefly occasioned by the vestiges of decayed leaves: at the top is a very large crown of leaves, disposed circularly like a full-blown rose, large, succulent, soft to the touch, and pliable, ending in obtuse points which are a little incurved: the flower-stalk comes out from the centre, and rises near two feet high, branching out from the bottom, so as to form a regular pyramid of flowers, which are of an herbaceous colour. It is a native of the Canary Islands, flowering in June and July.

A variety of this with variegated leaves was obtained from a branch accidentally broken from a plant of the plain sort, at Badmington, the seat of the Duke of Beaufort.

Culture.—The different herbaceous sorts are all capable of being increased without difficulty by planting their off-set heads, which should be slipped with a few root fibres to them, and planted in the spring season on rubbish rock-works, or other places, or in pots for variety: and the tender green-house sorts may be raised from cuttings of the branches and from seeds; but the first is the better method.

The cuttings should be made from the smaller branches in the early summer months, and be planted out in pots, or a bed of fine earth, in a warm shaded situation: where the cuttings are succulent, they should be laid in a dry place for a few days to heal over the cut part; they should be shaded from the sun; and those in pots lightly watered in dry weather: when they are become well rooted, they should be carefully removed into separate pots of a middle size, being placed in the green-house. Some forward these plants by means of bark hot-beds.

The seeds of the Canary kind should be sown in the autumn or early spring in pots of light mould, placing them in a garden-frame to protect them from frost, having the air freely admitted in mild weather: when the plants are come up, and have a little strength, they should be removed into small pots and placed in the green-house.

The first sorts are ornamental on walls, buildings, and rock-works, as well as in pots; and the last two kinds among other potted greenhouse plants.

SENA. See CASSIA.

SENECIO, a genus containing plants of the herbaceous, annual, and perennial kinds.

It belongs to the class and order *Syngenesia Polygamia Superflua*, and ranks in the natural order of *Compositæ Discoideæ*.

The characters are: that the calyx is common calyced, conical, truncate: scales awl-shaped, very many, parallel in a cylinder contracted above, contiguous, equal, fewer covering the base imbricatewise, the tops mortised: the corolla compound, higher than the calyx: corollets hermaphrodite, tubular, numerous in the disk: females ligulate in the ray, if any present: proper in the hermaphrodites funnel-form: border reflex, five-cleft: in the females, if any, oblong, obscurely three-toothed: the stamens in the hermaphrodites, filaments five, capillary, very small: anther cylindric, tubular: the pistillum in both: germ ovate: style filiform, length of the stamens: stigmas two, oblong, revolute: there is no pericarpium: calyx conical, converging: the seeds in the hermaphrodites solitary, ovate: pappus capillary, long; in the females very like the hermaphrodites: the receptacles naked, flat.

The species cultivated are: 1. *S. hieracifolius*, Hieracium-leaved Groundsel; 2. *S. Pseudo-China*, Chinese Groundsel; 3. *S. hastatus*, Spicewort-leaved Groundsel; 4. *S. elegans*, Elegant Groundsel, or Purple Jacobæa.

The first is an annual plant, with a round, channelled, hairy stalk, rising three feet high: the flowers in a state of terminating umbel, composed of dirty-white florets. It is a native of North America, flowering in August.

The second species has a perennial root, composed of some thick fleshy tubers, sending out many fibres on every side; from which come out some large cut leaves shaped like those of the turnep, but smooth: the flower-stalk slender, a foot and half high, sustaining at the top a few yellow flowers. It is a native of the East Indies.

The third has a herbaceous perennial stalk, branching out at the bottom, and rising about two feet and a half high; having narrow leaves at bottom, seven or eight inches long: the upper leaves are smaller, and embracing; they are very clammy: the upper part of the stalk divides into several very long peduncles, each sustaining one yellow flower. It is a native of the Cape, flowering most part of the summer.

The fourth species is an annual plant, having many herbaceous branching stalks, near three feet high: the flowers are produced in bunches on the top of the stalks; are large, the ray of a

beautiful purple colour, and the disk yellow. It is a native of the Cape, flowering from June to July till the beginning of autumnal frosts.

There are varieties with very double purple, and with equally double white flowers. The former is now chiefly cultivated.

There are many other species that may be cultivated for variety.

Culture.—The first and two last sorts are readily increased by planting cuttings of the branches in pots filled with fine mould in the summer season, shading them till they have taken root; and, as the winter approaches, removing them under the protection of the greenhouse, where they should remain till May, when they may be planted out in the borders or clumps.

They may likewise be raised from seed, which should be sown in the spring in pots, and placed in a gentle hot-bed.

The second sort should be more carefully attended, being raised from off-sets, which should be planted in pots in the spring season, and plunged in the hot-bed of the stove, where the plants should be constantly kept.

The first and two last sorts afford variety in borders, and among potted plants; and the second in stove collections.

SENGREEN. See SAXIFRAGA.

SENN. See CASSIA.

SENN, BLADDER. See COLUTEA.

SENN, SCORPION. See EMERUS.

SENSITIVE PLANT. See MIMOSA.

SERRATULA, a genus containing plants of the tall, hardy, herbaceous, perennial kind.

It belongs to the class and order *Syngenesia Polygamia Æqualis*, and ranks in the natural order of *Compositæ Capitatæ*.

The characters are: that the calyx is common oblong, subcylindrical, imbricate, with lanceolate, acute or obtuse, awnless scales: the corolla compound tubulous, uniform: corollets hermaphrodite, equal: proper one-petalled, funnel-form: tube bent in; border ventricose, five-cleft: the stamens have five capillary, very short filaments: anther cylindrical, tubulous: the pistillum is an ovate germ: style filiform, length of the stamens: stigmas two, oblong, reflex: there is no pericarpium: calyx unchanged: the seeds solitary, obovate: pappus sessile, feathered: the receptacle chaffy, flat.

The species cultivated are: 1. *S. Novboracensis*, Long-leaved Saw-wort; 2. *S. præalta*, Tall Saw-wort; 3. *S. glauca*, Glaucous-leaved Saw-wort; 4. *S. squarrosa*, Rough-headed Saw-wort; 5. *S. scariosa*, Ragged-cupped Saw-wort; 6. *S. spicata*, Spiked Saw-wort.

The first has a perennial root: the stalks several, channelled, seven or eight feet high; the leaves from four to five inches long, and one

inch broad in the middle, slightly serrate, downy on their under side, sessile: the upper part of the stalk divides into peduncles, sustaining purple flowers, which appear at the end of July. It is a native of North America.

The second species has a large, perennial, fibrous root: the stem branching, from four to seven or eight feet high: the leaves seven inches long, and an inch and half broad in the middle, ending in acute points, entire, hairy on their under side, sessile: the flowers in loose bunches at the end of the branches: the calyxes oval, composed of few scales terminating in bristles: the flowers are of a pale purple colour. It is a native of Virginia, Carolina, &c.

The third has a perennial root: the stalks six or seven feet high, purple and channelled: the leaves about three inches long, and an inch and half broad in the middle, ending in acute points, stiff, serrate, and of a light green on both sides: the flowers in a loose terminating corymb, purple, with roundish calyxes. It is a native of Maryland, Virginia and Carolina, flowering in October.

The fourth species has a tuberous root, from which comes out a single stalk, rising near three feet high: the leaves stiff, about three inches long, entire, rough to the touch, pale green on both sides: the upper part of the stalk is adorned with purple flowers, having oblong, rough, prickly calyxes, coming out from the side alternately; and the stalk is terminated by one head larger than the others. It is a native of Virginia, flowering in July and August.

The fifth has a large tuberous root, from which comes out one strong channelled stalk, three or four feet high: the leaves frequent, about three inches long, and half an inch broad: the flowers purple, in a long loose spike, coming out from the side upon pretty long blunt peduncles; they have large rough calyxes composed of wedge-shaped scales. The upper flowers blow first, and appear in August.

The sixth species has a tuberous root, from which comes out a single stalk from two to three feet high: the leaves very narrow, smooth, at bottom more than three inches long, but gradually diminishing to the top, sessile, and placed round the stalk without any order: the flowers purple, smaller than in the fourth and fifth sorts, sessile, and forming a long loose spike. It is a native of North America, flowering from August to October.

Culture.—These plants may all be increased by parting the roots and planting them out in the autumn when the stems decay, or in the spring; but the former is the better season. The old plants should not be parted oftener than every third year, and then not too small.

They are likewise all capable of being increased by seeds, when they can be had good, which should be sown in the autumn or early spring, in a border to the east, in slight drills. When the plants are a few inches high, they should be pricked out in nursery-rows to remain till the following autumn, and then planted out where they are to remain.

They afford ornament in the borders, clumps, &c. being planted to the middle or the back parts.

SERVICE TREE. See *SORBUS*.

SHADDOCK. See *CITRUS*.

SHADE, any thing that intervenes to obscure or protect from the rays of the sun. It is effected in various ways in gardening; as by mats, covers, &c.

SHADING OF PLANTS, the art of protecting plants of young and tender growths in seed-beds, &c. from the sun. It is a necessary work on many occasions, in warm, dry, sunny weather in spring and summer, &c. in pricking out various sorts of small young plants from seed-beds into nursery-beds, pots, &c. as well as small cuttings, slips, above-ground off-sets, pipings, &c. as likewise occasionally in transplanting any kind of more advanced plants, flowers, &c. into beds, or pots, in a hot, dry season; and sometimes to seed-beds of particular sorts of small or curious seeds in hot sunny days; also to plants in hot-beds, under frames and glasses, both of young and more advanced growths. It is the most commodiously and effectually performed by garden mats in a sort of awning over the beds, to plants in the full ground, or to those in pots placed close together; or sometimes to seed-beds, either in that way, or by being spread on the surface; in the latter method, being occasionally watered over the mats: or sometimes, in hot dry weather, by some loose straw litter strewn over seed-beds, which by screening the surface from the parching sun, and preserving the moisture in the earth, promotes a more quick, regular, and free germination in the seed; and when the plants are come up, the covering is soon drawn off lightly with a wooden or other rake. To plants under glasses in frames, &c. the occasional shading is effected either by mats spread thinly over the glasses, or sometimes by a little loose, long litter, shaken lightly over them, just during the fierce heat of the sun. In all cases the shade should not be made too thick, so as to darken the plants too much.

In the business of occasional shading, it is in general only to be continued in the warmest time of sunny days, generally longer to plants, cuttings, &c. which have not struck root, than those that are in a growing state; and in common

with all plants in the full ground, or others designed for placing in the open air, where occasional shading is necessary, it should be discontinued on evenings, mornings, and nights, that they may enjoy the benefit of the full fresh air at these times; as also the tender sorts, striking or advancing in growth under glasses, having occasional shading when the sun is powerful, in the warmer part of the day, should remain unshaded before and after that time, that they may receive the necessary beneficial influence of light and air in a proper degree. But in plants, cuttings, slips, &c. that have had occasional shading till they have struck good root, and begin to advance a little in a renewed growth, the shading should be mostly discontinued gradually, especially for those in beds, pots, &c. in the open ground, or others designed for transplantation, or for placing in pots, in the full air for the summer, according to their kinds: but in some small tender plants of slender growth, the occasional shading may probably be necessary in longer continuation, as till they acquire more strength; and to plants remaining all summer in hot-beds, or under frames and glasses, the continuance of occasional moderate shading in hot sunny days will be proper; but in most young plants, cuttings, &c. pricked out or planted as above, and designed for the full ground or open air, not continued under glasses, the having the benefit of occasional shade till well struck, is all they require.

The sorts of plants which require this kind of management are very numerous; but it is constantly mentioned in their culture where necessary.

SHALLOT. See ALLIUM.

SHIFTING OF PLANTS, the business of removing plants in pots from smaller into larger ones, &c. to give them fresh earth or mould. It is necessary occasionally in all plants in pots, to assist them with larger ones according as the advanced growth of the particular sorts renders it proper, and at the same time to supply an additional portion of fresh earth about the root fibres of the plants, to promote their growth; and sometimes for the application of fresh compost, either in part or wholly, from the plants having remained long unremoved, and the old earth in the pots being much decayed, or on account of some defect of growth in the particular plants.

In regard to the necessity of shifting, it is, in some degree, according to the advancing growth of the different sorts of plants: some sorts of a strong free growth require shifting once every year or two; others, more moderate growers, or of more settled growths, once in two or three years; and some large growing kinds, which are advanced to a considerable size, having been occasionally shifted, in their

increasing growth, from smaller into larger pots of different proportionable sizes, and some from large pots into tubs, of still larger dimensions, as large plants of the American aloe, orange and lemon tree kinds, &c. in that advanced state sometimes only need occasional shifting once in three or several years, especially when the pots or tubs are capacious, containing a large supply of earth, and are occasionally refreshed with some new compost at top, and a little way down round the sides about the extreme roots. And in some small slow-growing plants, as in many of the succulent tribe, shifting them once in two or three years may be sufficient: other sorts want shifting annually into larger pots, according as they advance in a free growth, as the hardy and tender kinds of herbaceous and shrubby plants, &c. And some of the tender annual flower-plants, cultivated in pots, and forwarded in hot-beds, being planted first in small pots, want shifting, in their increasing growth, into larger sizes, once or twice the same season, as from April to the beginning of June, when being shifted finally into the requisite full-sized pots, they remain during their existence.

But though large-grown plants, either of the shrub or tree kind, as well as other plants of large growths, after being finally stationed in the fullest sized large pots and tubs, succeed several years without shifting, they should in the interval have the top earth loosened, and down round the sides to some little depth, removing the loosened old soil, and filling up the pots, tubs, &c. with fresh earth, settling it close by a moderate watering.

The usual season for occasional shifting such plants as require it, is principally the spring and autumn, as from March to May for the spring shifting; and from August to the end of September for the autumn; though in plants that can be removed with the full balls of earth about the roots, it may be occasionally performed almost at any time; however, for any general shifting, the spring and autumn are the most successful seasons, as the plants then sooner strike fresh root; and many sorts preferably in the spring, by having the benefit of the same growing season, and that of summer.

In performing the business, it is mostly proper to remove the plants from the smaller to the larger pots, with the balls of earth about the roots, either wholly, or some of the outward old earth, the dry or matted radicle fibres only being carefully trimmed away, so as not to disturb the principal roots in the bodies of them, as by this means the plants receive but little check in their growth by the removal. Sometimes, when any particular plants, shrubs, or trees, &c. in their

pots, discover by their tops that they are in a declining state, as probably the defect may be either in the root, or the old balls of earth, it may be proper to shake all the earth entirely away, in order to examine the roots, and to trim and dress them as the case may require, re-planting them in entire fresh compost or mould.

In preparing for the business, where necessary to give larger pots, &c. it is proper to provide them of suitable sizes in some regular gradation larger than the old ones, according to the nature and growth of the plants, the whole being placed ready, with a proper quantity of fresh compost earth in proportion to the number and size of the plants intended to be shifted: then let these plants intended to be removed with balls, be taken out of their old pots separately, with the whole balls or clumps of earth about the roots as entire as possible; and when large or tolerably full, with a knife trim off some of the outward loosest earth, and the extreme fibres of the roots; but when small, and adhering together compactly, the whole may be preserved entire; and in either case, where there are very matted, dry, or decayed fibres surrounding the balls, they should be trimmed as it may seem necessary: in those of a fresh lively growth, the loose straggling parts only should be cut away: the requisite pruning, trimming, or dressing in the heads or tops should also be given where it may seem proper, according to the state of growth, and the natural habit of the different plants; but many sorts require little or none.

Having prepared the intended pots for the reception of the plants, by placing some pieces of tile or oyster-shell, &c. loosely over the holes at bottom, and laid in a little fresh earth two, three, or four inches deep or more, according to the size of the pot, the plant should be set in with its ball of earth, as above, filling up around it with more fresh mould, raising it an inch or two over the top of the ball; and giving directly a moderate watering to settle the earth close about the ball and roots regularly in every part, in a proper manner: in such cases where the ball in particular plants appears very compactly hard and binding, it may be proper to loosen it a little, by thrusting a sharp-pointed stick down into the earth in different parts, giving it a gentle wrench to open the earth moderately; or sometimes it may also be proper to trim away some of the old earth on the top and sides; then planting it as above, and filling up round and over the ball with fresh earth, and watering it afterwards.

In shifting hardy or tender, shrubby, succulent, or herbaceous plants, when any appear of a sickly, weak, or unhealthy growth, it may be advisable to clear off a considerable part of the

Vol. II.

outward old earth from the balls about the roots, or, in some cases, to shake it wholly away, that the defects in the growths, occasioned either by faults in the roots or in the earth, may be removed by pruning out any decayed or bad parts of the roots, and re-planting them wholly in fresh earth.

Sometimes particular sorts of plants in pots require shifting, more for the advantage of having fresh earth, than for want of new or larger pots; and as in this case some of the same pots may be still of an eligible size to re-pot them in, these pots should be well cleaned from all adhering parts of the old earth, and be replenished with entire new at the time of re-potting the plants; which being removed out of their pots, either with the entire balls about the roots, and part of the old mould cleared off all round, to admit of a larger portion of fresh earth in the pot at re-planting; or in some, appearing of an infirm or declining habit, the whole balls of old earth displaced clean to the roots; then having furnished the pots with fresh earth, the plants should be replaced in them, filling up the pot regularly with a sufficiency of the same fresh mould, and finishing with a moderate watering to settle the whole close about their roots.

After shifting, when the plants are not watered at the time, a moderate watering both to the earth in the pots to settle it close about the roots, and in most sorts highly over the tops or heads of the plants, should be given, in order to wash off any foulnesses; then the pots of plants should be set in their respective stations in the garden, &c.: the hardy kinds, if warm sunny weather, may be placed in a shady border for two or three weeks, till they have struck fresh root in the new earth: the tender sorts should be disposed in their places among the green-house and stove plants, or to have the benefit of shade in the middle of hot sunny days, till fresh struck, or probably some of the more tender particular sorts may require to be plunged in a hot-bed or bark-bed, especially some of the stove kinds: some principal sorts of the more curious or tender green-house plants, in order to expedite their fresh-rooting more effectually; and sometimes tender annuals in hot-beds, potted in their early young growth, may require to be replunged in the hot-bed to fresh strike, and forward them till June; but generally all the full ground or open air plants only require a little occasional shade in hot dry weather the first two or three weeks, and some shifted with full balls about the roots only need occasional watering: afterwards, on the whole, both the hardy and tender kinds should have repeated moderate waterings given them, according to their kinds.

SHOT INDIAN. See CANNA.

SIDA, a genus containing plants of the exotic, tender, herbaceous, perennial kind, for the hot-house.

It belongs to the class and order *Monadelphia Polyandria*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a one-leaved perianth, angular, half-five-cleft, permanent: the corolla has five petals, wider above, emarginate, fastened below to the tube of stamens: the stamina have very many filaments, united below into a tube, in the apex of the tube divided: anthers roundish: the pistillum is an orbicular germ: styles five or more; or else one many-cleft: stigmas headed: the pericarpium is a roundish-angular capsule, composed of five or more cells, (corresponding with the number of the styles or stigmas,) two-valved, awnless, acuminate or horned, opening above, or close, and finally separating: the seeds solitary, two, three, or five, roundish, mostly acuminate, convex on one side, angular on the other, fastened to the interior suture.

The species chiefly cultivated are: 1. *S. rhombifolia*, Rhomb-leaved Sida; 2. *S. periplocifolia*, Great Bindweed-leaved Sida; 3. *S. triquetra*, Triangular-stalked Sida; 4. *S. Abutilon*, Broad-leaved Sida; 5. *S. alba*, White-flowered Sida; 6. *S. cordifolia*, Heart-leaved Sida.

The first has the leaves lanceolate rhomb-shaped with the axils two-thorned. It is a native of the East Indies and Jamaica.

The second species has an annual root: the stem from two to four feet high, erect, simple, round, pubescent, sometimes divided towards the top into spreading branches: the leaves petioled, alternate, smooth, somewhat wrinkled, hoary beneath: the panicle terminating, half the length of the stem, erect, almost simple, spreading: the peduncles simply subdivided, alternate, filiform, the last one-flowered: the flowers pale, sometimes light purple. It is a native of the West Indies and Ceylon.

The third species is a shrub three feet in height, with subtomtose branches, having each of the three sides hollowed out with a blunt groove: the leaves cordate without angles, very soft, obscurely tomentose, bluntly serrate, acuminate: the peduncles axillary, one-flowered: the flower is of a yellow colour. It is a native of the West Indies.

The fourth species is in height about four feet, putting out some side branches towards the top: the leaves soft and woolly: the flowers axillary, on long peduncles. It is annual, and a native both of the East and West Indies, Virginia, and Siberia.

The fifth has the leaves round: the corolla is white with purple stigmas, and the tips of the petals purplish. It is annual.

The sixth has a hairy annual root: the stem simple, more than three feet high, sending out several erect branches from the sides: the leaves two inches and a half long, and two broad, of a light green colour, soft to the touch, on very long hairy footstalks: the calyx hairy: beaks of the seeds, when the corolla falls, prominent, in a bundle the length of the calyx: the capsules from seven to ten: the flowers small, of a pale obscure yellow- or sulphur-colour. It is a native of the East Indies and the Cape.

Culture.—These plants may be increased by seeds, which should be sown upon a moderate hot-bed in the early spring, or in pots deposited in them. In the first case, when the plants have attained some growth, they should be removed to another hot-bed and set out four inches apart each way, or into separate pots, replunging them in the hot-bed, being shaded till they have taken new root; a large proportion of free air being admitted in fine weather, and also frequent waterings: they should afterwards be gradually hardened to bear the open air in the summer season.

Some of them may also be raised from offsets and cuttings planted in pots in the summer season.

The fourth sort is sufficiently hardy to bear the open air: the seeds should be sown where the plants are to remain, as they do not bear transplanting well. It is an annual plant.

Some of the species do not flower till the second year; of course they should be placed in the stove in the autumn, and be managed during the winter as other tender exotic plants of the same nature.

They afford ornament among other potted plants in the stove, and the fourth sort in the borders.

SIDERITIS, a genus containing plants of the under shrubby, and shrubby exotic kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatae*.

The characters are: that the calyx is a one-leaved perianth, tubular, oblong, about half-five-cleft: segments acute, almost equal: the corolla one-petaled, almost equal: tube cylindrical, throat oblong, roundish: upper lip erect, bifid, narrow: lower lip trifid; lateral segments sharper, commonly smaller than the upper lip; middle segment roundish crenate: the stamina have four filaments, within the tube of the corolla, shorter than the throat, two of which are smaller: anthers roundish, two twin: the pis-

tillum is a four-cleft germ : style filiform, usually longer than the stamens : stigmas two : upper cylindrical, concave, truncate ; lower membranaceous, shorter, sheathing the upper : there is no pericarpium : calyx cherishing the seeds in its bosom : the seeds four.

The species cultivated are : 1. *S. Canariensis*, Canary Iron-wort ; 2. *S. Cretica*, Cretan Iron-wort ; 3. *S. Syriaca*, Sage-leaved Iron-wort.

The first has the stem five or six feet high, sending out several woody branches covered with a soft down : the leaves on long footstalks ; in young plants often five or six inches long, and two and a half broad near their base ; but in older plants not more than half that size ; they are very woolly, especially on their under side, which is white, but their upper surface is of a dark yellowish green : the flowers, which grow in thick whorled spikes at the end of the branches, are of a dirty white, and appear early in June : the plants frequently produce flowers again in autumn. It is a native of the Canaries and of Madeira.

The second species is a shrub with divaricating branches, very thickly tomentose and snow-white : the leaves cordate, crenate, tomentose on both sides, obtuse, very thickly tomentose and snow-white beneath, green above : the spike from the division of the branches, peduncled, pendulous, tomentose, snow-white together with the calyxes, which are blunt : the flowers about eight in each whorl. It is a native of the island of Crete or Candia.

The third has a short woody stem, with a few branches about a foot long : the leaves thick, wedge-shaped, very downy and white : the flowers in whorls towards the end of the branches, yellow with smooth downy calyxes. It has the appearance of a Sage, but is longer. The whole plant is covered with a very close white cotton. It is a native of the Levant, flowering from June to September.

There are other species that may be cultivated.

Culture.—These plants may be increased by seeds, cuttings and layers.

The seeds should be sown in pots in the spring, plunging them in a moderate hot-bed : when the plants have had some growth they should be removed into separate small pots filled with light mellow mould, being afterwards treated as other shrubby green-house plants.

The cuttings and layers may be planted out or laid down in the summer season, and when sufficiently rooted managed as the other sorts.

The third sort may be increased by planting the slipped heads either in pots or a shady border, to be afterwards removed into pots for protection in the winter in a frame.

They afford variety in green-house collections among other evergreen potted plants.

SIDEROXYLON, a genus containing plants of the shrubby, evergreen, exotic kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Dumosa*.

The characters are : that the calyx is a five-cleft perianth, small, erect, permanent : the corolla one-petalled, wheel-shaped : segments five, roundish, concave, erect : toothlet cusped, serrate, at the base of each division of the petal, tending inwards : the stamens have five awl-shaped filaments, length of the corolla, alternate with the toothlets : anthers oblong, incumbent : the pistillum is a roundish germ : style awl-shaped, length of the stamens : stigma simple, obtuse : the pericarpium is a roundish berry, one-celled : the seeds five.

The species cultivated are : 1. *S. inerme*, Smooth Ironwood ; 2. *S. lycioides*, Willow-leaved Ironwood.

The first in its native situation rises to the height of an apple-tree ; but in this climate it is rarely more than eight or ten feet high : the wood is so heavy as to sink in water, and being very close and hard, the name of Iron-wood has been given it : it divides into many branches, which are covered with a russet bark : the leaves about three inches long, and an inch and half broad in the middle, ending in points at both extremities, placed without order on the branches, having footstalks an inch long : they are smooth, of a lucid green, and continue all the year : the flowers come out in clusters from the side of the branches upon short footstalks, which branch out into several smaller, each sustaining a single flower, which is small and white. It flowers in July, and is a native of the Cape.

The second species is a tree with axillary solitary spines and alternate leaves : the peduncles axillary, one-flowered, very many, a little longer than the petioles : the calyx five-cleft, obtuse : the corolla funnel-form, five-cleft, obtuse ; with the segments concave, scarcely unfolded : nectary five-leaved, serrate, short, each lobe to each segment of the corolla : the stamens ten, awl-shaped, length of the nectary ; anthers sagittate : germ globular : style filiform ; stigma very small : the berry black, globular, from three- to five-celled, commonly abortive. It is a native of South America.

Culture.—These plants may be increased by seed procured from abroad, which should be sown in the spring in pots filled with fresh mould, and plunged in the tan-bed of the stove : when the plants have some growth, they should be removed into separate pots and be rephunged in the bark-bed.

They are sometimes raised from slit-layers and cuttings in the summer season; but they are tedious in forming roots in this way, and the plants are not so good.

The first is tender, affording variety in the stove; but the last is more hardy, and may sometimes be introduced in the shrubby borders in warm sheltered situations.

SILENE, a genus containing plants of the hardy herbaceous, of the annual and perennial kind.

It belongs to the class and order *Decandria Trigynia*, and ranks in the natural order of *Caryophyllei*.

The characters are: that the calyx is a one-leaved perianth, ventricose, five-toothed, permanent: the corolla has five petals: claws narrow, length of the calyx, margined: border flat, obtuse, often bifid: nectary composed of two toothlets in the neck of each petal, forming a crown at the throat: the stamens have ten awl-shaped filaments, alternately inserted into the claws of the petals, and later than the other five: anthers oblong: the pistillum is a cylindrical germ: styles three, simple, longer than the stamens: stigmas bent contrary to the sun's apparent motion: the pericarpium is a cylindrical capsule, covered, one- or three-celled, opening at top into five or six parts: the seeds very many, kidney-form.

The species cultivated are: 1. *S. armeria*, Common or Lobel's Catchfly; 2. *S. quinquevulnera*, Variegated Catchfly; 3. *S. pendula*, Pendulous Catchfly; 4. *S. muscipula*, Spanish Catchfly; 5. *S. viridiflora*, Green-flowered Catchfly; 6. *S. nutans*, Nottingham Catchfly; 7. *S. fruticosa*, Shrubby Catchfly.

The first is an annual plant with erect stalks, a foot and half high, for more than an inch below each joint very glutinous: the lower leaves broad, oblong, smooth, sessile: the flowers in terminating bunches, standing erect, and forming a kind of umbel. It is a native of Denmark, &c. flowering in July and August.

There are varieties with a bright purple flower, with a pale red, and with a white flower.

In the second, from a small fibrous annual root arise several flaccid spreading stems, round, hairy, and a little viscid; as are also the leaves in a slight degree: numerous flowers spring in an alternate order from the bosoms of the upper leaves, on pedicels which are erect, or but little divaricated even when the fruit is ripe: the petals are remarkable for the deep red spot in their centre, like a drop of blood. It is a native of the South of Europe.

The third is an annual plant, from whose root come out several branching stalks, near a

foot and half long, which trail upon the ground, opposite: the leaves oval, acute-pointed: the flowers come out singly from the axils, upon short peduncles; they are large, and of a bright red colour, resembling those of the common Wild Red Campion. It is a native of Sicily and Crete or Candia, flowering in May and June.

The fourth species has a biennial root: the stalk round, clammy, a foot and half high, having swelling joints: the leaves narrow and smooth, growing round the stalk in clusters: the upper part of the stalk divides into spreading branches by pairs, and has red flowers coming out singly from the axils, and sessile: the plant is extremely viscid. It is a native of the South of France, &c.

The fifth has a biennial root: the lower leaves roundish and hollowed like a spoon: those upon the stalks obtuse, and standing by pairs, threes or fours round the stalks; they are deep green, smooth and sessile: the stalks round, smooth, from two to three feet high: the flowers in loose spikes at the top, of a green colour. It is a native of Spain, &c. flowering in June and July.

The sixth species has a somewhat woody perennial root: the stems several, simple, (according to Mr. Woodward frequently branched from the root,) a foot or more in height, erect, leafy, round, pubescent, jointed at the base, viscid in the upper part, terminating in a forked panicle, the summit and branches of which all droop towards one side: the leaves lanceolate acute, quite entire, pubescent on both sides, of a palish green; the radical ones inclining to obovate, and forming thick tufts: the flowers drooping, white, of a delicate texture. It is a native of several parts of Europe, flowering in June and July.

The seventh has the stem low, shrubby, dividing into several short branches: the leaves smooth, ending in acute points: the flower-stalks rise about a foot high, and divide into spreading panicles, sustaining two and three flowers, of an herbaceous white colour. It is a native of Sicily, flowering in June and July.

Culture.—The annual and biennial sorts may be raised by seeds, which should be sown in the spring or autumn seasons, where the plants are to grow; but the latter is the better time. Some sow at both seasons, which may be a good practice. The seed should be put in in patches in the borders, clumps, &c.: when the plants are up they should be thinned to two or three plants in each clump and be kept clean from weeds. With the biennial sorts it is sometimes the practice to sow them in beds, and when the plants are up to remove them into nursery-rows

till the autumn, when they are planted out in the borders, &c.

The perennial sorts may likewise be increased from seeds in the same manner; but the usual way is by slips of the heads, and parting the roots, planting them out in shady places in the spring or early summer months. The shrubby sort may be increased by slips and cuttings of the branches or shoots, which should be planted out in similar situations in the spring and summer seasons.

They all afford ornament and variety in the clumps and borders of pleasure-grounds.

SILPHIUM, a genus containing plants of the tall-growing, herbaceous, perennial kind.

It belongs to the class and order *Syngenesia Polygamia Necessaria*, and ranks in the natural order of *Compositæ Oppositifoliæ*.

The characters are: that the calyx is common ovate, imbricate, squarrose: scales ovate-oblong, bent back in the middle, prominent every way, permanent: the corolla compound radiate: corolllets hermaphrodite in the disk many: females in the ray fewer: the proper of the hermaphrodites one-petalled, funnel-form, five-toothed; the tube scarcely narrower than the border:—of the females lanceolate, very long, often three-toothed: stamens in the hermaphrodites: filaments five, capillary, very short: anther cylindrical, tubular: the pistillum in the hermaphrodites: germ round, very slender: style filiform, very long, villose: stigma simple:—in the females, germ obcordate: style simple, short: stigmas two, bristle-shaped, length of the style: there is no pericarpium: calyx unchanged: the seeds in the hermaphrodites none:—in the females solitary, submembranaceous, obcordate, with the edge membranaceous, two-horned, emarginate: the receptacle chaffy: chaffs linear.

The species cultivated are: 1. *S. laciniatum*, Jagged-leaved Silphium; 2. *S. terebinthinum*, Broad-leaved Silphium; 3. *S. Asteriscus*, Hairy-stalked Silphium; 4. *S. trifoliatum*, Three-leaved Silphium.

The first has a perennial root: the stem twice the height of a man, as thick as the thumb, quite simple, smooth below, above rugged with brown tubercles and white spreading hairs, round: the leaves petioled, two feet in length and a foot in breadth, embracing at the base, pinnatifid; segments on each side four or five, distant, narrow, tooth-sinuate, rugged, with very solid ribs raised on both sides; margin of the upper leaves purplish: the calyx of ten scales, ending in large awl-shaped spines: the petals of the ray thirty, length of the calyx, with a bifid slender style: the florets of the disk yellow, many, separated by chaffs, attenuated at

the base, with a simple style. It is a native of North America, flowering from July to September.

The second species has two or three stems, strong, upright, annual, smooth; paniced above, but without any branches throughout the whole length, being beset with distant leaves: radical and lower cauline leaves large, heart-shaped, upright, rough, sharply toothed on the edges, and ciliated with very short hairs; they are very veiny, but not wrinkled: the footstalks are long, and embrace the stem at their base: the stem-leaves are similar, but scarcely hearted at the base, and the others are more oblong, and half embrace the stem: the peduncles are elongated, round, and mostly leafless; though a few of them are furnished with two opposite leaflets: the terminal flower on the stem flowers first, and when this begins to seed the lateral peduncles of the panicle begin to extend and proceed to flower: the smell of the flower, which is moderately large, and yellow, is similar to that of the Sun-flower. It is a native of North America, flowering in August and September.

The third has a perennial root: the stem four or five feet high, thick, solid, set with prickly hairs, and having many purple spots: the lower leaves alternate; upper opposite and sessile, rough, about two inches long, and an inch broad near the base, having a few slight indentures on their edges: the upper part of the stem divides into five or six small branches, terminated by yellow radiated flowers like those of the perennial Sun-flower, but smaller, having generally nine florets in the ray. It is a native of North America, flowering from July to September.

The fourth species has a perennial and woody root: the stems annual, rising five feet high or more in good land, of a purplish colour, and branching towards the top: the leaves oblong, rough, having some sharp teeth on the edges; they are from three to four inches long, and almost two broad; towards the bottom of the stem they stand by fours at each joint; higher up they are by threes, and at the top by pairs, sitting close to the stems: the flowers upon pretty long peduncles, solitary. It is a native of many parts of North America, flowering from July to October.

Culture.—They are all readily increased by parting the roots and planting them out in the autumn or spring, where they are to remain in the borders and clumps. They may also be raised by planting the slips in the same manner: they should be afterwards managed as the perennial Sun-flower.

They afford a good variety and effect among other perennial plants in the summer season.

SILVER BUSH. See ANTHYLLIS.

SILVER TREE. See PROTEA.

SIMPLER'S JOY. See VERBENA.

SINAPIS, a genus containing a plant of the hardy herbaceous annual kind.

It belongs to the class and order *Tetradynamia Siliquosa*, and ranks in the natural order of *Siligosæ* or *Cruciformes*.

The characters are: that the calyx is a four-leaved perianth, spreading: leaflets linear, concave-channelled, cruciform-spreading, deciduous: the corolla four-petalled, cruciform: petals roundish, flat, spreading, entire: claws erect, linear, scarcely the length of the calyx: nectarcous glands four, ovate: one on each side between the shorter stamen and the pistil, and one on each side between the longer stamens and the calyx: the stamens have six awl-shaped filaments, erect: two of them opposite, the length of the calyx, and four longer: anthers from erect spreading, acuminate: the pistillum is a cylindrical germ: style length of the germ, height of the stamens: stigma capitate, entire: the pericarpium is an oblong silique, torose below, rugged, two-celled, two-valved: partition for the most part twice the length of the valves, large, compressed: the seeds many, globular.

The species cultivated are: 1. *S. alba*, White Mustard; 2. *S. nigra*, Common or Black Mustard.

The first has an annual root: the stem strong, hard, nearly round, upright, branched, striated or finely grooved, set with numerous stiffish hairs pointing downwards, from a foot and half to two feet in height: the leaves petioled, alternate, pale green, rough with strong hairs on both sides, all deeply indented or lobed, the terminating segment very broad and large, and frequently a pair of small wings on the petiole: the lower ones deeply pinnatifid; the upper ones sublyrate: the flowers on loose racemes or bunches at the ends of the branches, on horizontal pedicels, which have four grooves or corners, and strong hairs pointing downwards. It is a native of Germany, &c.

It is generally cultivated in gardens as a sallad herb, with Cresses, Radishes, &c. for winter and spring use.

The second species has an annual small root: the stem upright, round, streaked, the upper part smooth, three or four feet in height, with many distant spreading branches: the leaves petioled, variously lobed and toothed; those next the root lyrate, rugged; on the stem smooth, the upper ones frequently simple, lanceolate and sharply toothed; the very uppermost quite entire. It is a native of Europe.

It is the flour of the seed of this plant that affords the common mustard for the table.

Culture.—The first sort is sown along with other small sallad herbs at all times of the year, sometimes every week or fortnight, in a bed or border of light earth, sown generally in shallow drills very thick, covering it very thinly with earth; and in winter, and early in spring, during cold weather, in hot-beds. The herbs are always cut for use whilst in the seed-leaf and but a few days old; otherwise they become too strong and rank-tasted for use. See SALLAD HERBS and SMALL SALLADING.

In order to have seed of this sort for garden use, it should be sown on an open spot of ground in March or April, either thinly in drills a foot asunder, or broad-cast all over the surface, and the plants be left to run up to stalk, when they will furnish ripe seeds in August.

But in order to raise the plants for the seed for mustard, the seeds should be sown in the spring, any time in March, in some open situation, either in the kitchen-garden or in open fields: in either case, having dug or ploughed the ground, the seed should be sown broad-cast all over the surface, and raked or harrowed in lightly; or it may be sown in shallow drills a foot asunder, and be slightly covered in: the plants soon come up, and when they have four or more leaves an inch or two broad, if they stand very thick, those sown in the broad-cast way particularly should be hoed and thinned, leaving them six or eight inches asunder, cutting up all weeds, repeating the operation once or more if necessary; after this the plants will soon spread and cover the ground, and shoot fast up to stalks for flowers and seed, which ripen in July or August, when the stalks should be cut or pulled up, and the seed, being properly hardened, and dried in the pod, should either be thrashed out directly, or stacked up dry and thrashed at occasional opportunities afterwards; but the first is the best method.

SISYMBRIUM, a genus containing a plant of the hardy herbaceous kind.

It belongs to the class and order *Tetradynamia Siliquosa*, and ranks in the natural order of *Siligosæ*, *Cruciformes* or *Cruciferae*.

The characters are: that the calyx is a four-leaved perianth: leaflets lanceolate-linear, spreading, coloured, deciduous: the corolla four-petalled, cruciform: petals oblong, spreading, commonly less than the calyx, with very small claws: the stamens have six filaments, longer than the calyx; of these two opposite a little shorter: anthers simple: the pistillum is an oblong filiform germ: style scarce; any: stigma obtuse: the pericarpium is a silique, long, incurved, gibbous, round, two-

celled, two-valved: valves in opening straightish, partition a little longer than the valves: the seeds very many, small.

The species is *S. Nasturtium*, Common Water Cress.

It has perennial roots, consisting of long white fibres, the lowermost fixed in the soil, the rest suspended in the water: the stems spreading, declining or floating, angular, branched, leafy: the leaves alternate, pinnate, somewhat lyrate, the terminating and upper leaflets being the largest: all the leaflets roundish, more or less heart-shaped, smooth, shining, waved or toothed, frequently tinged with a purplish brown hue: the flowers white, in a corymb, soon lengthened out into a spike: the pods shortish, on horizontal pedicels, but the pods themselves recurved upwards: the stigmas nearly sessile: but according to Curtis, the root is annual. Withering marks it as biennial. It is a native of Europe, Asia, &c.

Culture.—This may be effected by parting the roots, or by seed. In the first method, while the plants are young, a quantity of slips should be made with root-fibres to them, and be planted out immediately in a shallow, trickling, watery situation, when they will readily strike roots, seed, and increase themselves.

The seed should be collected during the summer season, and sown in the same places; or, which is better, the plants, with the ripened seeds upon them, be thrown into them, where they will strike root, and shed their seeds for future increase.

These plants are in much esteem as winter and spring salad herbs.

SISYRINCHIUM, a genus containing plants of the flowery perennial kind.

It belongs to the class and order *Monadelphia Triandria*, and ranks in the natural order of *Ensatæ*.

The characters are: that the calyx is a common ancipital spathe, two-leaved: valves compressed, acuminate: proper several, lanceolate, concave, obtuse, one-flowered: the corolla one-petalled, superior, six-parted: segments obovate with a point, from erect spreading: three outer alternate, a little wider: the stamina have three filaments, united into a subtriquetrous tube shorter than the corolla, distinct at the top: anthers bifid below, fastened by the back: the pistillum is an obovate inferior germ: style three-sided, length of the tube: stigmas three, thickish, awl-shaped at the top, erect: the pericarpium is an obovate capsule, rounded, three-sided, three-celled, three-valved; with the partitions contrary: the seeds several, globular.

The species are: 1. *S. Bermudiana*, Iris-leaved Sisyrinchium; 2. *S. anceps*, Narrow-leaved Sisyrinchium.

The first has a fibrous root, from which arise some stiff sword-shaped leaves, four or five inches long and half an inch broad, of a dark green colour: from among these comes out the stalk (scape) six inches high; it is compressed, and has two borders or wings running the whole length, and three or four spear-shaped leaves embracing it; these grow erect, and are hollowed like the keel of a boat: the stalk is terminated by a cluster of six or seven flowers, on short peduncles, and enclosed in a two-leaved, keel-shaped sheath, before they open; they are of a deep blue colour with yellow bottoms, which, when fully expanded, are an inch over. It is a native of Bermuda.

The second species has a perennial fibrous root, from which arise many very narrow spear-shaped leaves, about three inches long, and scarcely an eighth of an inch broad, of a light-green colour: the stalks about three inches high, very slender, compressed and bordered, having short, narrow, sword-shaped, embracing leaves: they are terminated by two small pale-blue flowers, inclosed in a two-leaved sheath, upon longer peduncles than those of the first sort, flowering about the same time. It is a native of Virginia.

It is observed, that the leaves, stalks, and flowers of the first sort are three times as large as in the second, and the sheath incloses six or seven flowers; whereas the second has rarely more than two, and these expand only for a short time in the morning, while in the former they continue open the whole day.

Culture.—These plants may be increased by seeds and parting the roots: in the former method the seeds of the first sort should be sown in the autumn as soon as they become ripe, on a border which has an eastern aspect, in drills at three or four inches distance, covering them about half an inch with fine mould: they should afterwards be kept clean from weeds with care. They succeed best in a loamy soil in a shady situation, and where the ground has not been manured.

In the latter sort the seeds should be sown in pots, in order that they may be protected in the green-house.

The first affords ornament in the large open borders and clumps, and the latter among other green-house plants.

SIUM, a genus containing a plant of the hardy, herbaceous, esculent kind.

It belongs to the class and order *Pentandria*

Digynia, and ranks in the natural order of *Umbellales* or *Umbelliferae*.

The characters are: that the calyx is an universal umbel, various in different species: partial spreading, flat: involucre universal many-leaved, reflex, shorter than the umbel, with lanceolate leaflets: partial many-leaved, linear, small: perianth proper scarcely observable: the corolla universal uniform: floscules all fertile: proper of five index-cordate, equal petals: the stamina have five simple filaments: anthers simple: the pistillum is a very small germ, inferior: styles two, reflex: stigmas obtuse: there is no pericarpium: fruit subovate, striated, small, bipartite: the seeds two, subovate, convex and striated on one side, flat on the other.

The species cultivated is *S. sisarum*, Skirret.

It has the root composed of several fleshy tubers as large as a man's little finger, and joining together in one head: the lower leaves are pinnate, having two or three pairs of oblong leaflets terminated by an odd one: the stalk rises a foot high, and is terminated by an umbel of white flowers, which appear in July, and are succeeded by striated seeds like those of Parsley, ripening in autumn. It is a native of China, &c.

It was formerly much cultivated for the roots, which were eaten boiled, and stewed with butter, pepper, and salt; or rolled in flower and fried; or else cold with oil and vinegar, being first boiled.

Culture.—It may be raised either by seeds or slips from the roots, but the first is the best method, as in the latter mode the roots are apt to become sticky: the seeds should be sown about the beginning of April, either in broadcast over the surface, or in drills, the ground being previously well dug to a good depth; light and rather moist land being chosen for the purpose. The plants mostly appear in five or six weeks, and when they can be sufficiently distinguished by their leaves, the ground should be well hoed over, in the same manner as for carrots, the plants being properly thinned out to the distance of five or six inches. The hoeing should be repeated as often as necessary, in dry weather.

In the autumn when the leaves begin to decay the roots will be fit for use, and will continue so till the spring.

In the offset method, the old plants should be dug up in the spring before they begin to shoot, the side shoots being then slipped off with an eye or bud to each, planting them in rows a foot apart, and four or five inches distant in the rows; they should afterwards be cultivated as the others.

These roots are prepared by boiling, and eaten

in the same manner as above, or as carrots and parsnips. They are wholesome, but not in such request as formerly.

SLIPS, such portions of plants as are slipped off from the stems or branches for the purpose of being planted out.

A number of plants, both of the woody and herbaceous kinds, are propagated by slips, which is effected in the woody kinds by slipping off small young shoots from the sides of the branches, &c. with the thumb and finger, instead of cutting them off with a knife, but there is no material difference, in the success or future growth, between slips and cuttings, only the former in small young shoots is more proper to be shipped off by the hand, which in numerous small, shrubby plants will grow; but is more commonly practised on the lower ligneous plants, such as sage, winter-savory, hyssop, thyme, southernwood, rosemary, rue, lavender, and others of low shrubby growths. The best season of the year for effecting the work is generally in spring and beginning of summer, though many sorts will grow if planted at almost any time, from the spring to the latter end of the summer, as shown in speaking of their culture.

In performing the work of slipping in these sorts, the young shoots of but one year's growth, and in many sorts the shoots of the year should be chosen as growing the most readily, even when to plant the same summer they are produced, especially the hard-wooded kinds: but in the more soft-wooded plants, the slips of one year's growth will also often readily grow; being careful always to choose the moderately growing side-shoots situated on the outward part of the plants, from three to six or eight inches long, slipping them off close to the branches, and clearing off the lower leaves; then planting them either in a shady border, if in summer, and watered, or so as they can be occasionally shaded in hot sunny weather, especially small slips, inserting the whole two parts of three in the ground, giving occasional water, in dry warm weather, till properly rooted; and then towards autumn, or in spring following, transplanting them where they are to remain.

But in planting slips of the shoots of tender shrubby exotics of the green-house and stove, many sorts require the aid of a hot-bed or bark-bed, to promote their emitting roots more effectually, as shown in their respective culture; but some others of the shrubby kinds, such as geraniums, will root freely in the natural earth in summer; and many of the herbaceous tribe, producing bottom-rooted offsets for slips, as aloes, &c. also readily grow, either with or

 ion when
 week or

ten or twelve days old, whilst they remain
 mostly in the seed-leaf, being then cut up close
 to the ground for use; for, being mostly of a
 warm relish, in which consists their chief ex-
 cellence for winter and spring salads, if suffered
 to grow large, and run into the rough leaf,
 they become of a disagreeable, strong, hot
 taste; but when used as above, they eat ex-
 ceedingly tender, with an agreeable warm fla-
 vour.

For the purpose of salading, these plants
 may be obtained young at all times of the year,
 in spring and summer in the open ground, and
 in winter under the shelter of frames and glasses,
 and occasionally on hot-beds.

This sort of salading is procured by sowing
 the seeds of the different plants at different times
 throughout the whole year.

Winter and Spring Culture.—In the winter
 and spring it may be raised either in hot-beds or
 in the open borders, and, according as it may be
 required, early or late; but when it is required
 as early as possible, it must be sown in hot-beds
 under frames and lights, &c. or in a bed or bor-
 der of natural earth under glasses.

The sowing should be made on hot-beds any
 time in December, January, or February; and
 where a considerable supply is daily required, may
 be continued sowing every week or fortnight in
 hot-beds till March, or during the cold weather,
 for which a moderate hot-bed of dung should
 be made for one, two, or more garden-frames,
 but only half a yard or two feet depth of dung,
 according to the temperature of the season, as the
 heat is only required to bring up the plants
 quickly, and forward them a week or two in
 growth, placing a frame directly thereon, and
 moulding the bed all over with light rich earth,
 five or six inches thick, making the surface level
 and smooth; when, if it is to be forwarded as
 much as possible, directly sow the seed, which
 may be done either in drills as shallow as pos-
 sible, about two or three inches broad, and flat
 at the bottom, and three inches asunder, sowing
 the seeds of each sort separate and very thick,
 so as almost to cover the ground, only just co-
 vering them with earth; or, to make the most
 of the bed, it may be sown all over the surface,
 previously smoothing it lightly with the back of
 the spade, the different sorts separately, and all
 very thick; and after pressing them all even and
 lightly down with the spade, covering them very
 thinly with earth, by sifting over as much light
 mould as will only just cover the seed; and as
 soon as the sowing is performed in either me-
 thod, putting on the lights: the seeds soon
 come up, as in two or three days or less, being
 careful at this time to give vent to the steam

arising in the bed, as well as to indulge the plants with plenty of free air daily, either by tilting the lights in the back or front, according to the temperature of the weather, or by drawing the lights a little down, or taking them quite off occasionally in mild days at first; for the hot-bed being yet new, there will be a considerable steam arising; and the salading coming up very thick, unless due vent be given to pass off the steam and admit fresh air, they will be apt either to burn or fog (as the gardeners term it), and mould off as fast as they come up. Such hot-beds, however, as are not fresh made, do not require this precaution; but in new-made beds it must be strictly observed till the salading is all fairly come up, and as long as the strong steam continues: the plants will mostly be fit for use in a week or ten or twelve days from the time of sowing the seed.

In order to have a proper succession, the sowing in the hot-beds should be repeated every week or fortnight during the cold weather; the same hot-bed sometimes retaining its heat will admit of two sowings, by sowing again as soon as the first crop is gathered: however, to obtain a regular supply daily, it is necessary to continue making fresh hot-beds occasionally.

Where only a small quantity may be wanted at a time, and there is the convenience either of cucumber and melon hot-beds, or a hot-house, &c., some seed of each sort may be sown in pots or boxes, and placed in these hot-beds or the stove, just to bring up the plants fit for use.

Where there are not frames and glasses, hand- or bell-glasses may be used, or the bed be arched over with low hoop-arches, in order to cover with mats every night, and in bad weather.

And where there are no hot-beds, in cold weather, early in the spring, part of a warm border, or a bed of light earth in a sunny situation may be prepared, for garden-frames and lights, hand-glasses, &c. raising the ground somewhat to the sun; and having dug it, and raked it fine, sow the seed as above, covering it lightly with earth; and having set on the frames and glasses, the seeds will soon come up, and the salading be ready a considerable time sooner than in the open ground.

Culture in the full Ground.—From about the end of February, or beginning of March, according to the forwardness or mildness of the season, Small Salading may be sown in the open ground, repeating the sowings every week or ten days; the first sowing being performed on a warm border; continuing the sowings in that situation till the beginning or middle of April, when it may be sown in any of the open quarters, and in which the sowings may be repeated

weekly, or once a fortnight, as required; but according as the hot weather approaches, sowing in a somewhat shady situation.

The ground for each sowing in the different situations should be properly dug, and the surface raked smooth and even.

These sowings are mostly made in shallow drills, which should be drawn with a small hoe either with the corner, or held edge-ways downward, horizontally, drawing the drills along evenly, as shallow as possible, and flat or level at bottom, at three or four inches asunder, in which the seed should be put evenly all along the bottom, each sort separate, and very thick, covering them in evenly with the finest of the mould, not more than a quarter of an inch deep; or if the smaller seeds are but just covered, it is sufficient; for when sown very thick, if deeply covered with mould, the plants do not rise regularly.

In these early spring sowings, on cold nights and all bad weather it is proper to cover the ground, both before and after the plants begin to rise, with large mats, which will be better if supported on low hoop-arches, or ranges of pegs stuck in the ground just high enough to support the mats a little from the earth, by which a more effectual as well as forward crop is produced.

In the later sowings, when dry warm weather commences, it is proper to give occasional waterings.

It is likewise sometimes necessary, where the surface of the ground becomes crusted, from wet, &c. as the plants rise thick, to slightly brush over the surface with the hand or a soft broom, so as to reduce the surface mould a little, and promote their coming up.

Summer Sowings.—When the sowings are practised in summer, they should be made more frequently, and the ground be kept watered occasionally, both before and after the plants are come up.

Autumn Sowings.—The sowings may be continued in the open ground all September and October, also occasionally in November in mild seasons; and until towards the middle of October they may be made in any open situation; but from the middle or latter end of October and in November they must be on warm south borders, performing the sowings as above; and in cold nights bestowing a covering of mats, or hand-glasses, &c. repeating the sowings every week or ten days, or a fortnight, as required.

In gathering young salading, it should be cut carefully close to the ground while quite young, in performing which, a large pair of scissors is very convenient.

In order to have good seed, some plants should be preserved annually for the purpose.

le. It is a
d August.

The fourth species has a thick stalk, taper, rising by claspers ten or twelve feet high: the leaves thick, three inches and a half long, and an inch and half broad: the flowers axillary in round bunches, and succeeded by black berries. It is a native of Virginia and Carolina, flowering in July.

The fifth has the stems taper: the leaves four inches long, and two inches and a half broad at their base, having seven longitudinal veins: the flowers come out in long loose bunches from the side of the stalks, and the berries are black. It is a native of North America, flowering in June and July.

In the sixth the leaves have the form of the hederaceous plants, but not the consistence, for they are thin: the little umbels of small flowers are on very long slender peduncles, from the bottom of the leaves. It is a native of North America, flowering in July.

The seventh has a taper stem, very strong, armed with short stiff spines, and rising twenty feet high by their claspers: the leaves thick, four inches long, and three inches and a half broad at their base, ending in an obtuse point, and having five longitudinal veins: the flowers in close bunches: the berries red: the root horizontal, creeping far and wide, with oblong tubers, knobbed and warted, sometimes branched, pale or reddish within, half a foot long, roundish, scattered. It should be chosen full, heavy, and compact, of a reddish colour, and free from rottenness; for it is much subject to be gnawed by worms. It is a native of China, Cochinchina, and Japan.

The eighth species has a shrubby stem, very long, slender, with few scandent branches: the leaves small, the lower cordate, the upper ovate-lanceolate, three-nerved, quite entire, flat, with the margin bent back: the flowers in lateral umbels: the berries red: the root is horizontal, simple, thick, short, tubercled, with many long undivided fibres: but according to Browne, small, and divided into a number of slender branches. It is a native of Virginia, Jamaica, China, &c.

Culture.—The six first hardy sorts may be increased by slipping the roots, layers, and seed.

In the first mode the stalks arising from the roots should be slipped with roots to each in the autumn, and be planted out either in nursery-rows for a year or two, or, which is better, where they are to grow.

In the layer method, the stalks should be laid down in the common manner in autumn, and when well rooted, in the autumn following be taken off and planted out as above.

The seed should be obtained from abroad, and

be sown in pots filled with fine mould in the spring, being plunged in a hot-bed to forward their coming up: when the plants have attained some growth they should be planted out and managed as the others.

The two last tender sorts may be increased by layers of the young shoots, and dividing the roots, which should be laid down, or planted out in the spring season in pots, in order to have the culture of other woody green-house plants of the same nature.

The layers will be ready to take off in the spring following.

The first sorts are proper for shady situations, borders, &c. and the latter afford variety in the green-house collections.

SMYRNium, a genus containing a plant of the herbaceous esculent kind.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Umbellatæ* or *Umbelliferae*.

The characters are: that the calyx is an universal umbel, unequal, becoming daily bigger: partial erect: the involucre universal none: partial none: perianth proper scarcely apparent: the corolla is universal uniform: floscules of the disk abortive: proper of five lanceolate petals, slightly bent-in, keeled: the stamina have five simple filaments, length of the corolla: anthers simple: the pistillum is an inferior germ: styles two, simple: stigmas two, simple: there is no pericarpium: fruit oblong, striated, bipartite: the seeds two, lunulate, on one side convex, marked with three angles, flat on the other.

The species cultivated is *S. Olusatrum*, Common Alexanders.

It has a biennial root, fleshy, branched: the whole herb of a pale bright green, often of a sickly yellowish cast, smooth, succulent, in flavour something like Celery, but more strong and bitter: the stem round, strong, deeply grooved: the upper leaves ternate, lower triterminate; leaflets wide, varying in form, gashed and serrate, subpetioled: the common petiole dilated at the base, ventricose, and nerved: umbels terminating, globular, many-rayed: the flowers small, numerous, irregular, greenish yellow: the fruit large, black, remarkably gibbous, deeply grooved. It is a native of France, Spain, Italy, &c.

Culture.—These plants are raised from seeds, which should be sown in the spring in any light soil and open situation, in shallow drills, fifteen or eighteen inches asunder; and when the plants are come up two or three inches high, be thinned out to six or eight inches distance in the rows, to give them room to shoot up strong; when earth must be drawn up about them gradually, in order to blanch or whiten them a little below, that they may be more crisp and

tender for autumn and winter use; but as in the spring following they shoot out again vigorously, some earth should be hoed up close about each plant, and in three or four weeks they will be blanched fit for use.

It is used as a culinary plant, when blanched, in the same manner as celery, and is of a warm aromatic quality.

SOIL, the mould or earth in which plants grow. For the general purposes of gardening, those of the dry, light, friable, loamy kinds are the most valuable, especially when they have been well impregnated and enriched with manure. See **EARTH, COMPOST, AND MANURE.**

SOLANUM, a genus containing plants of the herbaceous, shrubby, and tuberous-rooted, esculent kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Luridæ*.

The characters are: that the calyx is a one-leaved perianth, half-five-cleft, erect, acute, permanent: the corolla is one-petalled, wheel-shaped: tube very short: border large, half-five-cleft, from reflex flat, plaited: the stamina have five awl-shaped filaments, very small: anthers oblong, converging, subcoalescent, opening at the top by two pores: the pistillum is a roundish germ: style filiform, longer than the stamens: stigma blunt: the pericarpium is a roundish berry, smooth, dotted at the top, two-celled; with a convex fleshy receptacle on each side: the seeds very many, roundish, nestling.

The species cultivated are: 1. *S. Lycopersicum*, Love-Apple, or Tomato; 2. *S. Æthiopicum*, Ethiopian Nightshade; 3. *S. Melongena*, Large-fruited Nightshade, or Egg Plant; 4. *S. Dulcamara*, Woody Nightshade, or Bitter-sweet; 5. *S. verbascifolium*, Mullein-leaved Nightshade; 6. *S. Pseudo-Capsicum*, Shrubby Nightshade, or Winter Cherry; 7. *S. quercifolium*, Oak-leaved Nightshade; 8. *S. mammosum*, Dug-fruited Nightshade; 9. *S. Indicum*, Indian Nightshade; 10. *S. Carolinense*, Carolina Nightshade; 11. *S. sodomium*, Black-spined Nightshade; 12. *S. sanctum*, Palestine Nightshade; 13. *S. tuberosum*, Tuberous-rooted Nightshade, or Common Potatoes.

The first is an annual plant, with an herbaceous, branching, hairy stalk, rising to the height of six or eight feet if supported, otherwise the branches will fall to the ground: the leaves pinnate, of a very rank disagreeable odour, composed of four or five pairs of leaflets terminated by an odd one, cut on their edges, and ending in acute points: the flowers axillary on pretty long peduncles, each sustaining several yellow flowers, forming a single long bunch. The fruit is smooth, but varies in form, size and colour, from which Miller has formed two sorts.

The first of these is commonly cultivated in the South of Europe to put into soups and sauces, to which it imparts an agreeable acid flavour: the fruit is very large, compressed both at top and bottom, and deeply furrowed all over the sides, and of a red or yellow colour.

The latter round, about the size of a large cherry, either yellow or red. It is a native of South America, flowering from July to September.

The second species has an annual root: the stem stiffish: the leaves a hand in length, and blunt: the fruit red, large, depressed, so deeply furrowed as to be in a manner cut into lobes, hard: the branches diffused: the leaves ovate-oblong, sinuate-repand: the flowers solitary and violet. It is a native of China.

The third has an annual stem, thick, twisted, two feet high, with the branches reclining: the leaves ovate, sinuate, large, few, scattered, on thick petioles: the flowers pale violet; peduncles axillary, thickened, bent down, one-flowered, most commonly solitary, but not unfrequently two or three together: the berry large, shining, two-celled, many-seeded, esculent. It is a native of Asia, Africa, and America.

There are varieties with oblong violet-coloured fruit, with an oblong white large fruit; with a globular violet-coloured fruit, and with a globular white or variegated fruit.

The fourth species has a perennial root, woody, according to Dr. Beddoes, smelling like the Potatoe: the stem shrubby, roundish, branched, twisted and climbing to the height of several feet: the leaves alternate, petioled, ovate-lanceolate, quite entire, smooth, soft, veiny; the lower cordate, the upper more or less hastate: the flowers in racemes or cyme-shaped panicles, but not properly in cymes, opposite to a leaf or terminating, nodding, very elegant, purple with two green dots at the base of each segment, and the segments reflexed: the berries elliptic, scarlet, very juicy, bitter and poisonous. It is a native of Europe, Africa, &c. flowering in June and July.

There are varieties with flesh-coloured, with white flowers, and with variegated leaves.

The fifth is an unarmed tree, above the height of a man, with a trunk as thick as the human arm: but according to Miller it only rises with a smooth shrubby stalk six or eight feet high, covered with a brown bark, and divides into many branches, which have spear-shaped leaves three inches and a half long and an inch and half broad; they have a few sinuated indentures on their edges, and end in acute points; they are smooth, and of a light-green colour: the flowers are produced in small umbels from the sides of the stalks, standing erect; they are pretty large, white, and the petal is cut into five star-pointed segments. It is a native of America.

The sixth rises with a strong woody stalk four or five feet high, and divides into many slender stiff branches, having spear-shaped leaves turning backward: the flowers are white, and grow in small umbels, or singly on the side of the branches, to which they sit close; they appear from June to September, and are succeeded by berries as large as small cherries, which ripen in winter. It is a native of the island of Madeira.

There are varieties with red, and with a yellowish fruit.

The seventh has the stems angular, erect, rugged: the leaves oblong, decurrent into the petiole, veined, smooth, rugged beneath, pinnatifid: the peduncles branched: the corollas violet-coloured, blunter than in *Dulcamara*, with two greenish spots at the base of each lobe: anthers yellow, shorter than the style: the berries ovate. It is a native of Peru, flowering in July.

The eighth species rises with a prickly herbaceous stalk three or four feet high; the spines are strong and crooked; the leaves are large, angular, woolly, and armed with the like spines; the flowers are produced in bunches from the side of the stalks; they are of a pale blue colour, and are succeeded by yellow fruit, the shape and size of a Catherine Pear inverted. The plant is annual here. It grows common in all the West India Islands, where it is called Bachelor's Bear.

The ninth has the stem shrubby, two or three feet high, sending out several woody branches armed with short, strong, yellowish spines: the leaves an inch and half long, and an inch broad, woolly on both sides, and angularly indented, armed with spines on both sides along the midrib: the flowers come out in longish bunches from the side of the stalks, and are blue: the berries round, of a gold colour, as large as cherries. It is a native of the East and West Indies.

The tenth species has the stem in a manner shrubby, but yet annual: the leaves rugged, scarcely tomentose, entire at the base, sinuate

with sharpish angles, and spines on the midrib, not at the sides: the racemes longer than the leaves, loose, simple: the berries round, the size of a large pea, yellow when ripe. It is a native of Carolina, flowering in July.

The eleventh has a strong thick shrubby stalk, which rises from two to three feet high, sending out many short thick branches, closely armed with short strong yellow spines on every side: the leaves are about four inches long and two broad; are cut almost to their midrib in obtuse segments, which are opposite, regular, and formed like winged leaves; these segments have several obtuse indentures on their edges; are of a dark green colour, and armed with the same sort of spines as those on the stalks, on both sides: the flowers come out in small bunches on the side of the branches, are blue, appearing in June and July, and are succeeded by round yellow berries, as large as walnuts. It grows naturally at the Cape of Good Hope.

The twelfth species has the stem tomentose, ash-coloured, with thick straight short yellowish prickles, tomentose except at the end: the leaves ovate, shorter on one side of the base, tomentose, thick, blunt; the young ones pinnately sinuate, whitish at the edge, having three prickles on the rib: the petioles are prickly underneath: the peduncles from the side of the stem: the primary pedicel with the calyx spiny, the rest male and unarmed: the corolla, like that of Borage, purplish-blue. It is a native of Palestine.

The thirteenth is well known for its tuberous root: the stem from two to three feet in height, succulent, somewhat angular, striated, slightly hairy, frequently spotted with red, branched; the branches long and weak: the leaves interruptedly pinnate, having three or four pairs of leaflets, with smaller ones between, and one at the end larger than the rest; the leaflets are somewhat hairy, and dark green on the upper surface: the flowers are either white or tinged with purple; or, according to Gerarde, of a light purple, striped down the middle of every fold or welt with a light show of yellowness: the fruit is a round berry, the size of a small plum, green at first, but black when ripe, and containing many small flat, roundish, white seeds. It is probably a native of Peru.

The principal varieties may be distinguished into two kinds—as the red-rooted and white-rooted sorts; the subvarieties of which are extremely numerous; but for garden purposes the following are the most useful:

The Early Dwarf-red—the Round-red—the Ohlong red—the Pale-red—the Blood-red—the Irish-red, or Painted Lord—Old Winter-red—Rough-red—and Smooth-red.

Early Forcing Potatoe—the Early Dwarf-white—Brown Early—Cumberland Early—Early Scot—Golden Dun—Early Champion—White Blossom—Manly White.

Kidney White and Red—Red-nosed—True White—Flat White—Superfine White Early.

Culture.—The three first species, which are annual, may be raised from seed, which should be sown in the early spring on hot-beds moulded over to the depth of six or seven inches with light rich mould, in drills, or pots plunged into the beds. When the plants come up, they should be properly thinned, have a pretty free admission of air, and occasional waterings; and the Love Apple kinds, when they have attained some growth, as five or six inches, and the weather becomes settled warm, should be removed into the open ground, planting them in a warm sheltered border, placing them at a considerable distance. Some may be trained against a south fence to have the advantage of the full sun: they should always be supported by some means or other to show themselves, and ripen their fruit. But the egg plants should be pricked out when a few inches in height into another hot-bed prepared for the purpose, at the distance of four or five inches; and some may be put in separate pots and plunged in the bed, giving water and shade till they are fresh rooted: the waterings should be duly repeated, and fresh air freely admitted when the weather is fine: it may also be requisite to remove them with balls about their roots on to a third hot-bed in order to have them very fine and strong: the frame should be raised as they advance in growth, and when the weather becomes fine and hot they should be gradually hardened, and finally set out in the pots, &c. where they are wanted.

The fourth sort may be increased by layers and cuttings, which may be laid down or planted out in the autumn or spring, where they will be well rooted by the following autumn, when they may be taken off and removed into nursery-rows, or where they are to grow.

The eight following sorts may be increased by seeds, which should be sown thinly in rich light earth in the early spring in small pots, plunging them in the hot-bed under frames and glasses, watering them frequently, when the plants will soon come up, admitting fresh air daily; and when the plants are about two inches high, they should be pricked out upon another hot-bed, giving water and shade till they are fresh-rooted; and some may be put into pots, plunging them in the bed. As the warm weather advances, they should be gradually hardened to the open air, so as to be set out into it about the middle of the summer.

Holing-in planting.—This is performed with a spade. A man having a light handy spade, and beginning at one end of the line, takes out a spit of earth, forms a small aperture four or five inches deep, another person directly following after drops a set in the hole, the earth of the next spit immediately covers it up, and so on to the end.

Furrow-planting.—This is performed by the spade, by turning over or taking out a spit of earth all along, putting in the dung, and then dropping the sets in the furrow immediately upon it, and with the next spit turning the earth in upon the sets of the first; and in another furrow, two feet from this, dropping another row of sets, which are covered in as above, and so on till the whole is finished.

Trenching-in.—This is sometimes practised in light ground, and is effected as the person proceeds in digging or trenching the ground, being trenched in the common way, each trench two spades wide, and one spade deep, placing one row of potatoes in each trench: beginning at one end of the ground, opening a trench the proper width and depth, as above, then paring in the top of the next trench deeply, putting it with some good dung in the bottom of the first, levelling it evenly, then digging along about half the width of the next or second trench, turning the earth into the first upon the dung, only two or three inches in depth, and upon which lay the potatoe-sets in a row along the middle a foot or more asunder; then digging along the rest or whole width of the said second trench a moderate spade deep, turning the earth of it into the first trench, over the sets, three or four inches deep; this done, dung the bottom of the open trench, and proceed with the digging and planting as before; and thus continue trench and trench to the end.

Bedding-in.—This is sometimes done in low wettish land, for the sake of raising the beds, and sinking the alleys deep enough to drain off the too copious moisture, and is thus performed: The ground is divided into four, five, or six feet wide beds, with alleys two or three feet wide between bed and bed; and the beds being dug, the potatoe sets are placed upon the surface in rows lengthwise; and then the alleys

dug out a spade deep, casting the earth over the sets about three or four inches thick; or the alleys may be first dug out to raise the beds, and the sets then planted with a dibble in the common method: thus by either of these methods, in wet ground, the alleys being sunk, and the beds raised, the alleys drain off the redundant moisture, which might rot the sets before they begin to sprout.

This method of planting is sometimes performed on grass sward, marking out beds as above, with alleys between of proportionable width; then, without digging the beds, the potatoe sets are placed immediately upon the sward, at proper distances; the alleys being then dug and the spits turned grass-side downward upon the beds over the sets, covering them the proper depth as above, in which, if any additional depth is wanted, it may be supplied from the under earth of the alleys; and thus the sets being between two swards, grow, and often are productive of very good crops if permitted to have full growth.

In the after-management where weeds begin to overrun the ground, two or three hoeings should be given to kill them and loosen the surface of the soil; and where the plants have some growth, some hoe up a ridge of earth close to each side of every row of plants in the first or second hoeing, to strengthen their growth more effectually, and render them more prolific, as the bottom of the stalks so landed up generally emitting roots in the earth that become productive of potatoes the same as the principal roots.

In October, when the potatoes are full grown, they should be wholly taken up before they are attacked by frost, and deposited in some dry apartment for keeping: some may however be taken up before for occasional use: this business is usually performed by a three-pronged fork.

When it is intended to raise new varieties from seed, some of the first-flowering plants should be marked, the seed should be gathered in autumn when full ripe, and in the March or April following sown in some light soil, in an open situation, in shallow drills, a foot asunder; and when the plants come up, they should be kept clear from weeds till autumn, when, about the end of October or beginning of November, the roots may be taken up, selecting the finest and largest, which preserve in sand till spring; then plant them in the common way, and by autumn following they will have made proper increase, and attain full perfection; when their properties must be determined.

SOLDANELLA, a genus containing a plant of the low herbaceous perennial kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Primulæ*.

The characters are: that the calyx is a five-parted perianth, straight, permanent; segments lanceolate: the corolla one-petalled, bell-shaped, widening gradually, straight: mouth torn into many clefts, acute: the stamina have five awl-shaped filaments: anthers simple, sagittate: the pistillum is a roundish germ: style filiform, length of the corolla, permanent: stigma simple: the pericarpium is an oblong capsule, round, obliquely striated, one-celled, opening by a many-toothed top: the seeds numerous, acuminate, very small: the receptacle columnar, free.

The species is *S. alpina*, Alpine Soldanella.

It has a perennial fibrous root: the leaves almost kidney-shaped, about three quarters of an inch over each way, of a dark green colour, on long footstalks: among these arises a naked flowerstalk or scape, about four inches long, sustaining at the top two small open bell-shaped flowers, with the brim cut into many fine segments like a fringe: the most frequent colour is blue, but it is sometimes snow-white. It flowers in April, and the seeds ripen in July. It is a native of the Alps.

There is a variety which has all the parts smaller; the petiole is shorter and more slender, and the leaves are not so much rounded, but gradually widen from the petiole.

Culture.—This is increased by parting the roots in the autumn about September, planting them in pots or in a cool shady situation, where the soil is of a moist loamy kind, being frequently watered when the season is dry, and kept from the sun.

The seeds soon after they become ripe may also be sown in pots or boxes filled with the above sort of mould, being placed in the shade, and frequently watered. The plants rise in the spring, and in the autumn following should be removed into separate pots, to have the protection of a frame in winter. They succeed best in a northern aspect.

These plants afford variety among other potted plants.

SOLDIER-WOOD. See *MIMOSA*.

SOLIDAGO, a genus containing plants of the tall, herbaceous, flowering, perennial kind.

It belongs to the class and order *Syngenesia Polygamia Superflua*, and ranks in the natural order of *Compositæ Discoidæ*.

The characters are: that the calyx is oblong, imbricate, common: scales oblong, narrow, acuminate, straight, converging: the corolla is compound radiate: corollets hermaphrodite tubular, very many, in the disk:—female ligu-

late, fewer than ten, (commonly five) in the ray: proper of the hermaphrodite funnel-form, with a five-cleft, patulous border:—female ligulate, lanceolate, three-toothed: the stamens in the hermaphrodites: filaments five, capillary, very short: anthers cylindrical, tubular: the pistillum in the hermaphrodites: germ oblong: style filiform, length of the stamens: stigma bifid, spreading:—in the females: germ oblong: style filiform, length of the hermaphrodite: stigmas two, revolute: there is no pericarpium: calyx scarcely changed: the seeds in the hermaphrodites solitary, obovate-oblong: seed-down capillary:—in the females very like the others: the receptacle flattish, naked.

The species cultivated are: 1. *S. Virgaurea*, Common Golden-rod; 2. *S. Canadensis*, Canadian Golden-rod; 3. *S. altissima*, Tall Golden-rod; 4. *S. Mexicana*, Mexican Golden-rod; 5. *S. viminea*, Twiggy Golden-rod; 6. *S. bicolor*, Two-coloured Golden-rod; 7. *S. rigida*, Hard-leaved Golden-rod; 8. *S. cæsia*, Maryland Golden-rod; 9. *S. flexiculis*, Crooked-stalked Golden-rod; 10. *S. sempervirens*, Narrow-leaved Evergreen Golden-rod.

The first has a perennial root, of long simple fibres: the stem very various in height, from ten inches to three feet, commonly branching into a panicle, more or less flexuose, never entirely stiff and straight, leafy, angular, striated, a little downy; at the base round and often purple: the leaves elliptic-lanceolate, somewhat rugged, and stiffish; those next the root wider, on longer petioles, and more widely serrate; stem-leaves for the most part indistinctly crenate-serrate, sometimes almost quite entire, varying in size, often recurved; the upper ones gradually diminishing into lanceolate downy bracts: all somewhat hairy, or covered with short stiff down, paler underneath; footstalks winged: the flowers in terminating and axillary erect clusters or corymbs, forming a dense leafy pubescent panicle, which varies extremely as to luxuriance and number of flowers; in a barren soil and on mountains being shorter, more dense and less compound. They are of a golden colour. It is a native of Europe, Siberia, and Japan, flowering from July to September. It has sometimes the names of Wound-wort and Aaron's rod.

There are several varieties; as the purple-stalked broad-leaved, which has the stalks stiff, purplish brown, two feet high: the panicles axillary and terminating; each flower on a long slender footstalk, pale yellow, appearing at the beginning of August: the leaves lanceolate, almost four inches long, and a quarter of an inch broad, deeply serrate, pale green beneath.

The Common Golden-rod, which has the lower leaves ovate-lanceolate, two inches long and an

inch broad, slightly serrate, on pretty long footstalks: the stems slender, a foot and half high; with small, narrow, entire, sessile leaves: the flowers in panicked bunches, clustered together, forming a thick erect spike, appearing in August and September. The narrow-leaved, which has the stalk round, smooth, a foot and half high: the leaves narrow-lanceolate, an inch and quarter long, and an eighth of an inch broad, almost entire, sessile: the flowers in small clustered bunches from the axils, to which they sit very close; and the stalk is terminated by a roundish bunch. The Dwarf Golden-rod, which has the lower leaves indented: the stalk seldom more than a foot high, branching out almost from the bottom: the branches terminated by short, clustered, erect spikes: the leaves on the stem and branches very narrow, acute-pointed and entire. The Welch Golden-rod, which has the lower leaves narrow-lanceolate, an inch and half long, and a quarter of an inch broad, smooth, slightly serrate, a little hoary on the under side: the stalk about six inches high, with the same sort of leaves on it, only smaller: the flowers in roundish clustered terminating spikes, much larger than those of the common sort, and appearing five or six weeks earlier in the season.

The second species has the stalks round, smooth, and two feet high; the leaves narrow and rough, with three longitudinal veins, two inches and a half long, and a quarter of an inch broad in the middle, sessile, ending in acute points, and having sometimes a few slight serratures: the flowers in a roundish terminating panicle, the lower spikes of which are reflexed, but those at the top erect and joined very close. These appear in July. It is a native of Canada.

The third has the stems numerous, straight, rigid, from three to four feet and a half high, the thickness of a straw or more at the base, round, slightly streaked, hirsute, clothed from top to bottom at short distances with leaves, which are widish, oblong, pointed, rough, at their upper and lower parts thinly crenate, in the middle serrate, the serratures minutely crenate; those on the upper branches not serrate, but only minutely crenate; they are green on both sides, with a few oblique veins, and are hairy along the nerve and veins at the back, but without hairs every where else: the flowers very many, on the upper branches, in long rod-like spikes, somewhat reflexed, having four, five, or six florets in the ray: they appear in August and September. It is a native of New England, Virginia, and Carolina.

There are several varieties; as the Tallest Golden-rod—the Hairy Golden-rod—the Recurved Golden-rod—the Virginia Golden-rod.

The fourth species has oblique stalks, a foot

and half high, smooth, with a brown bark : the leaves smooth, spear-shaped, entire, three inches long, and three quarters of an inch broad : the flowers come out on branching footstalks on the side of the stalks, are ranged on one side, and have a few small leaves under the flowers, which appear at the end of August. It is a native of North America.

The fifth has smooth erect stalks, a foot and half high : the leaves narrow, smooth, entire, dark green : the flowers in close compact panicles at the top of the stalk ; spikes short, clustered : the flowers large, bright yellow, appearing in September. It is a native of North America.

The sixth species has the lower leaves oval, six inches long, and three broad, ending in acute points, serrate, having several strong longitudinal veins on long footstalks which have leafy borders or wings : the stalks a foot and half high, branching out almost from the bottom, garnished with small, spear-shaped, entire leaves : the branches grow erect, are closely furnished with small leaves below, and are terminated by short close spikes of white flowers ; or rather, having a yellow disk and a white ray, in close racemes. It is a native of North America, flowering in September.

The seventh has the stalks two feet high : the lower leaves ovate, stiff, smooth and entire, four inches long, and two inches and a half broad, on footstalks four inches in length ; those on the upper part of the stalk are spear-shaped, entire, and embrace the stalk half round : the flowers in loose, spreading, terminating panicles ; spikes short, clustered, bright yellow, appearing in August. It is a native of New England.

The eighth species has the stalk slender, smooth, a foot and half high : the leaves narrow-spear-shaped, two inches long, and half an inch broad, indented on their edges, and ending in acute points : the flowers in a loose terminating panicle, with the spikes closer and thicker towards the top. It is a native of Maryland, flowering in September.

The ninth has the lower leaves four inches long, and almost two broad ; their footstalks two inches long, having a membrane or wing on each side : the stalk rises two feet high ; they are slender, smooth, and of a light purple colour : the leaves ovate-lanceolate, indented, near two inches long, and three quarters of an inch broad, of a pale green on their under side : the flowers are produced in short bunches from the axils almost the whole length ; the lower spikes are an inch long, but the upper ones are almost round : the flowers are of a brimstone colour, and appear late in August. It is a native of Canada.

The tenth species is remarkable for its red stalk, higher than a man, with very smooth and

somewhat fleshy leaves, a little rugged at the edge, continuing the whole winter ; it flowers very late, so that in the Northern countries the frost commonly prevents them from opening. It is a native of North America.

Culture.—These plants are all readily increased by slipping or parting the roots, and planting them out in the autumn or winter soon after their stems decay, or very early in the spring before they begin to shoot ; but the former is the better season, in the places where they are to grow : they succeed in almost any soil or situation, and afterwards require only to be kept clean from weeds, and to have the decayed stems cut down when they begin to decay in the autumn. When they have increased considerably in the roots, they should always be slipped as above.

In planting out they require much room, as they spread considerably.

They afford considerable variety and ornament in larger borders and clumps.

SOLOMON'S SEAL. See *CONVALLARIA*.

SOPEBERRY. See *SAPINDUS*.

SOPEWORT. See *SAPONARIA*.

SOPHORA, a genus containing plants of the herbaceous, flowery, perennial, and shrubby exotic kinds.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are : that the calyx is a one-leaved perianth, short, bell-shaped, gibbous at the base above : mouth five-toothed, oblique, obtuse : the corolla papilionaceous, five-petalled : standard oblong, gradually wider, straight, reflexed at the sides : wings two, oblong, appendicled at the base, length of the standard : keel two-petalled, with the petals conformable to the wings, the lower margins approximating and boat-shaped : the stamens have ten filaments, distinct, parallel, awl-shaped, length of the corolla within the keel : anthers very small, rising : the pistillum is an oblong germ, cylindrical : style size and situation of the stamens : stigma obtuse : the pericarpium is a legume very long, slender, one-celled, knobbed at the seeds : the seeds very many, roundish.

The species cultivated are : 1. *S. tetraptera*, Wing-podded Sophora ; 2. *S. microphylla*, Small-leaved Shrubby Sophora ; 3. *S. alopecuroides*, Fox-tail Sophora ; 4. *S. australis*, Blue Sophora ; 5. *S. tinctoria*, Dyer's Sophora ; 6. *S. alba*, White Sophora ; 7. *S. tomentosa*, Downy Sophora ; 8. *S. occidentalis*, Occidental Sophora ; 9. *S. japonica*, Shining-leaved Sophora ; 10. *S. capensis*, Vetch-leaved Sophora ; 11. *S. aurea*, Golden-flowered Sophora ; 12. *S. myrtillifolia*, Round-leaved Sophora.

The first is a magnificent tree, displaying its pendulous branches of large golden flowers in May and June. It is a native of New Zealand.

The second species is a smooth tree, with small leaves almost wedge-shaped; the flowers large and yellow; the legume compressed, torulose, flat at the back and belly, keeled at the sides with longitudinal membranes. It is a native of New Zealand, flowering in May and June.

The third has a perennial creeping root, from which arise several erect stalks from three to four feet high: the leaves unequally pinnate: the flowers pale blue and small, in long axillary spikes standing erect close to the stalk: they smell sweet. It is a native of the Levant, flowering in July and August.

The fourth species has a herbaceous stem, most commonly decumbent: the leaves cuneate-oblong, smooth, yellowish green; the stipules ensiform, longer than the shortest petiole; the flowers are blue. It is a native of Carolina, flowering in June and July.

The fifth has a perennial root, from which arise several stalks about a foot and half high, sending out from the bottom a great number of small branches: the flowers come out towards the end of the branches in short spikes; are yellow and appear in July. It is a native of Barbadoes and Virginia.

The sixth species has the stem even, high, dark purple: the leaves, like those of Laburnum, even, elliptic, smooth on both sides, an inch and half long: the stipules scarcely any: the raceme a foot long, pendulous: the flowers white, the size of those of Laburnum. It flowers in June, and is a native of Virginia and Carolina.

The seventh species has a downy stem, six or seven feet high: the leaves unequally pinnate, composed of five or six pairs of leaflets: the flowers in short loose axillary spikes, large and yellow, not unlike those of Spanish Broom, void of scent: the pods larger, woolly, five or six inches long, having four or five large swellings, in each of which is a roundish brown seed as big as a pea. It is a native of Ceylon.

The eighth is a shrub, with a round hoary-pubescent stem, and round spreading subtomentose branches, six or seven feet in height: the leaves on alternate, long, spreading, round, hoary petioles, thickened at the base: leaflets opposite, mostly six-paired with an odd one, entire, flat, hoary, white tomentose beneath, on short round petioles: the flowers in a sort of spike: the peduncle terminating, erect, a foot long, simple, round, many-flowered: flowers close, biggish, peduncled, yellow. It is a native of the West-Indies; flowers there in May and June.

The ninth species has the branches round, even, purplish: the leaves alternate, unequally

pinnate: leaflets subopposite, on very short petioles, oblong, blunt with a point, quite entire, glaucous beneath, smooth, spreading an inch long: the flowers on panicle racemed branchlets, of a white colour. It is a native of Japan.

The tenth is a tender pubescent shrub, when more advanced in its wild state naked: the leaves alternate, unequally pinnate: leaflets twenty-three, narrow-lanceolate, equal, quite entire, shining above, subtomentose beneath: the raceme terminating, composed of white recurved flowers. It is a native of the Cape.

The eleventh species is a shrub the height of a man: the root has the smell and taste of liquorice: the stem upright, round, tubercled, gray: branches alternate, spreading, like the stem: the leaves alternate, unequally pinnate, spreading, eight inches long: petioles round on one side, channelled on the other, pubescent: the leaflets from twelve to fifteen pairs, opposite, on short petioles, those of the outmost longer, quite entire, one-nerved, bright green, paler beneath, spreading very much, flat: the stipules linear, acute, pubescent, brownish, erect, permanent: the racemes axillary, solitary, peduncled, spreading, bracted, pubescent, four or five inches long: the flowers alternate, nodding, yellow, eight or nine lines in length, on round pedicels jointed at the top. It is a native of Africa, and flowers there in July.

The twelfth has a shrubby, round, leafy, even stem: the branches almost upright, tomentose, somewhat angular towards their tops: the leaves scattered, on short petioles, ten lines long, and four broad, quite entire, rounded at the end with a reflexed point, grooved above and keeled beneath, coriaceous. On each side of the petiole an awl-shaped tomentose stipule, twice as long as the petiole: the flowers towards the end of the branches from the axils of the leaves, solitary, on peduncles the length of the adjacent leaf, white-tomentose; seldom two-flowered. It is a native of the Cape, flowering from November to January.

Culture.—The first five sorts are hardy, and may be increased by seeds or parting the roots.

The seeds should be sown in the spring in pots of fine mould, and when the plants are come up they should be removed into separate pots, till they have obtained sufficient strength, when they may be planted out where they are to grow.

The roots may likewise, in many of the sorts, be parted at the same season and planted in pots, or where they are to remain.

The first and second sorts may also be raised from cuttings and layers, planted or laid down at the same season. These, when planted against a wall, so as to be protected from frost in winter, succeed very well.

All the other sorts are tender, and require the hot-house or stove. They are increased by sowing the seed in the early spring, in pots filled with fine mellow light mould, and plunged in the hot-bed under glasses, or in the bark-bed. When the plants have advanced a little in growth, they should be removed into separate pots, filled with soft loamy mould, being well watered and replunged in the bark-bed till fresh rooted; being afterwards managed as other exotic stove plants, with but little water. They likewise sometimes succeed by layers and cuttings, treated in the same manner.

The first sorts afford variety in the borders and among potted plants, and the latter in stove collections.

SORB TREE. See *SORBUS DOMESTICA*.

SORBUS, a genus containing plants of the ornamental tree kind.

It belongs to the class and order *Icosandria Trigynia*, and ranks in the natural order of *Pomaceæ*.

The characters are: that the calyx is a one-leaved perianth, concave-spreading, five-cleft, permanent: the corolla has five petals, roundish, concave, inserted into the calyx: the stamina have twenty awl-shaped filaments, inserted into the calyx: anthers roundish: the pistillum is an inferior germ: styles three, filiform, erect: stigmas headed: the pericarpium is a soft globular berry, umbilicate: the seeds three, somewhat oblong, distinct, cartilaginous.

The species cultivated are: 1. *S. aucuparia*, Mountain Service, Mountain Ash, Quicken Tree, Roan Tree: 2. *S. domestica*, True Service or Sorb; 3. *S. hybrida*, Bastard Service, or Mountain Ash.

The first is an elegant tree, of slow growth; the wood tough and close-grained, not very hard; the bark smooth and gray; the young branches purplish brown; the leaves unequally pinnate: leaflets (five, six, seven or eight pairs) serrate except at the base, smooth above, and nearly so beneath, except a few fine scattered hairs; their under side is also glaucous: they are sessile, lanceolate; the middle ones longest, and the odd one is rather oblong-ovate: the midrib is channelled, and often purple. And, according to Miller, the leaves on the young trees in the spring are hoary on their under side, but about midsummer the hoariness goes off, and those upon the older branches have very little at any season: the flowers are in large, terminating, pubescent corymbs, very much branched: the fruit bright red or scarlet when ripe, nearly round, the size of a large pea, juicy, with an astringency. It is a native of the colder parts of Europe, &c.

The leaves make a pretty variety when mixed

with other trees in plantations: it is also handsome when in flower, and in the autumn, when in fruit; but the blackbirds and thrushes are so fond of it, that they devour it before it is well ripe.

The second species is a tree of a middling size, not unlike the first, of very slow growth, not flowering till it arrives at a great age; the wood is very hard: the leaves alternate, composed of from six or seven to nine pairs of opposite, sessile, ovate or oblong, equal leaflets, with a terminating one of the same size; all entire at the base, serrate from about half way to the end, smooth above, downy beneath, but that downiness goes off towards autumn: the flowers in terminating panicles, subcorymbed, tomentose: the fruit pear-shaped, reddish and spotted, extremely austere, and not eatable till it is quite mellowed by frost or time, when it becomes brown and very soft. It is a native of the warmer parts of Europe, flowering in May.

There are varieties in the fruit: as with apple shaped fruit; with pear-shaped fruit; with oval fruit; with turbinate fruit; and with compressed fruit.

The third is a middle-sized tree: the leaves lobed in front, pinnate at the base, serrate, without any stipules, smooth above, white-tomentose beneath: the corymbs terminating, tomentose, many-flowered: the flowers white: the styles three, or sometimes two only: the fruit as in the first, but a little larger.

Culture.—These plants are all capable of being raised from seed, and also by layers; but the first is the best method.

The seeds, when well ripened in the autumn, should be sown on small beds of light fine ground in the nursery, either in drills or over the surface, covering them in to the depth of about an inch. When the plants rise in the following or second spring, they should be kept clear from weeds, and when of a year's growth, be planted out in nursery-rows, to remain till of a proper size for planting out.

The second sort is sometimes sown in large pots and forwarded in a hot-bed, so as to be sooner fit for planting out in nursery-rows.

In the layer method, some of the best trees should be cut down near to the ground while young, by which young shoots will be sent off, which should be laid down in the usual way in the autumn or spring season, where they readily strike root, and become proper for being planted out in nursery-rows in one year. In order to continue any particular variety, this method must constantly be adopted.

In cultivating the second sort for the purpose of fruit, the best method is by grafting or budding upon stocks of any of the sorts raised as above, or upon pear stocks.

These trees in rearing should be trained for standards, each with a single upright stem, in the nursery, till from three to six or eight feet high, when they are proper for any plantation, and may be transplanted as required.

They may be introduced in any large shrubbery or other ornamental plantation, and in those of forest-trees. Some of the domestic Services may also be introduced as fruit-trees in gardens and orchards, principally as standards, but occasionally in espaliers, &c. in both of which they should be planted and managed as apple- and pear-trees, permitting the standards to shoot freely above into full heads; the others being regulated according to their order of training. They will produce plentiful crops of fruit annually, after some time, to gather in autumn. In gathering of which for the table, it is proper to lay some in the fruiter, &c. a little time, to mellow, become soft and tender, in which state it is eatable, and of an agreeable taste and flavour.

SOUP HERBS, such as are made use of in soups and other culinary preparations. Various sorts of herbaceous vegetables are in estimation for this purpose, a list of which may be useful in assisting the memory in furnishing the garden with the proper sorts; but under the denomination of Soup Herbs, all the sorts of Pot-herbs used occasionally in soups and broths, &c. are included, as well as several sorts used as Salad-herbs.

The principal sorts are: Celery, Endive, Leeks, Lettuce, Spinach, Green and White Beet, Chard Beet, Orach, Borage, Bugloss, Burnet, Chervil, Sorrel, Parsley, Coriander, Pot-Marigold, Thyme, Winter Savory, Summer Savory, Pot or Winter Marjoram, Sweet Marjoram, Spear-Mint, Tarragon, Basil, Love-Apple or Tomatoes.

In all of which, except the Marigold and Love-Apple, the leaves are the only useful parts; but in the Marigold the flowers are the only part used, and in the Love-Apple the fruit. All the sorts, except the last two, (Basil and Love-Apple) are of a hardy temperature, and may be easily raised in the natural ground; and the greater part are biennials and annuals, that re-

quire to be raised from seed every year; but the Thyme, Winter Savory, Pot or Winter Marjoram, Sorrel, Mint, Burnet, and Tarragon, are perennials of many years' duration, being raised in some sorts both by seeds and slips, but in others principally by slips; and the Basil and Love-Apple, being tender annuals, require to be raised from seed in a hot-bed. See the *Cultures of the different sorts*.

SOWING OF SEEDS, the practice of putting seeds into the ground; in which different methods are made use of, according to the sorts: as Broad-cast sowing and raking-in, Drill-sowing, Bedding-in sowing, &c.

The first is the most common and expeditious method of sowing, both for many of the principal crops to remain, and for transplantation; and is performed by sowing the seed with a spreading cast evenly all over the surface of the ground, either in one continued plat or divided into beds, which is immediately raked with a large rake to bury all the seeds a due depth in the earth, some requiring to be raked in as light as possible, others half an inch or an inch or more deep, according to their sizes, &c.

In preparing for this method of sowing, the ground is previously dug over in the common way, making the surface level with the spade as the work proceeds, and, according to the nature of the seed, sowing it as soon as possible afterwards.

This sort of sowing should generally be performed in dry weather, particularly the early sowings in winter and spring; but in hot weather, in summer and autumn, it may often be eligible to take advantage of sowing immediately after a shower or moderate rain.

As to the sowing the seed in the Broad-cast way, it is effected occasionally both with an open and locked hand. In the former case, it is performed by delivering the seeds with an open hand, and broad-spreading cast, as practised in sowing corn in the open fields, previously stepping out the ground in breaks, or certain widths, as a guide to sow with the greater regularity; proceeding with the sowing along each space with a regular step and cast, giving the hand a proper sweeping cant forward, fully expanded at the delivery of the seeds, making them spread abroad evenly in every part; and thus proceeding up one space and down another till finished; which method is practised in large kitchen grounds in sowing any considerable space in one continued plat.

But the latter is practised occasionally, both in sowing large continued plats of ground, and narrow beds, &c. but more generally the latter; especially when intended sowing them bed and bed separately, or on narrow borders, and other

small plats of ground, commonly sowing or delivering the seeds with a locked or close hand, discharging them from between the fore-finger and thumb, opening or pinching the thumb more or less, according to the size and nature of the seeds and thickness they require to be sown, giving the hand a sort of jerking turn, or cant forward, at the delivery, to cause the seeds to spread regularly.

As soon as the seeds are sown they should be directly raked in, before the surface of the ground is rendered either too dry by the sun or wind, or made too wet by rain, in a regular and even manner, so as to bury them sufficiently according to their kinds, all large stones, lumpy clods, and rubbish being cleared off; smaller or larger rakes being used, as they may be necessary. See RAKE.

But previous to the raking in the seeds sown on the general surface in one continued space, where the ground is loose, light, and dry, and in a dry season, it is sometimes the practice, after sowing, to tread them in evenly by treading the ground all over lightly and regularly with the feet. It is also sometimes proper to pare up the loose earth of the alleys an inch or two deep, and spread it thinly over the surface. The work of treading in the seeds is performed with the feet nearly close together, taking short regular steps, treading the surface all over, once in a place, with but small spaces between the steppings.

But in extensive market kitchen-gardens, where large tracts of ground are sown at once, instead of raking in the seed, they, for the sake of expedition and cheapness, have light short-tined harrows to draw with men, with which they harrow in the seeds; and sometimes in light dry ground, and a dry surface, they afterwards roll the ground with a light wooden roller, to close and smooth the surface over the seeds more effectually, performing it when the surface is a little dried so as not to adhere to the roller. And in large garden-farms in fields, where they commonly plough and harrow the ground for the reception of the seeds, they practise only the Broad-cast sowing in continued tracts for almost all their esculent seeds, except peas, beans, and kidney-beans; the ground being prepared by ploughing, and afterwards rough-harrowed, to smooth the surface moderately, the seeds being then sown in the spreading open-handed manner, and harrowed in either with a light short-toothed horse-harrow, or by men for particular crops; when, if very dry weather, they roll the surface afterwards with a wooden roller, drawn by horses, &c. to smooth the surface.

The second method of sowing is necessary for many sorts of seeds, both esculent, flower, tree and shrub kinds in the nursery, both for the plants to remain where sown, and for

transplantation, which is performed in drills from a quarter or half an inch, to two or three inches deep, according to the sizes and sorts of seeds, which being sown evenly along the bottom of the drill, the earth is drawn evenly over them with a hoe or rake, the depths as above, and the surface lightly raked smooth. This mode is always proper for large kinds of seeds, such as peas, beans, kidney-beans, and many large kinds of tree and shrub seeds, nuts, and berries; it being not only the most ready method of committing those large seeds to the ground the proper depth, but, by being in rows at a distance, best suits the nature of the growth of these sorts of plants and their methods of culture. Many kinds of small seeds are also the most conveniently sown and cultivated in drills; such as several of the kitchen-garden plants, as parsley, chervil, coriander, all the sorts of small-salading, and sometimes spinach, beet, &c. also some of the aromatics, when designed as edgings; and also occasionally in rows in beds, both to remain and for transplanting, such as thyme, savory, hyssop, &c. likewise many sorts of flower-seeds for transplantation, and sometimes to remain. It is performed by drawing the drills with a common drawing-hoe, larger or smaller, in proportion to the sorts of seeds to be sown, setting a line as a guide to draw the drills straight by, which are drawn of different depths, as the sorts and sizes of the seeds may require, and at proportionable distances, from three or four inches to as many feet, according to the nature of the plants. Sometimes, when very small drills are required for fine or small seeds, to be sown in a bed, border, or hot-bed, it is done with the end of the finger, or with the end of a small flat stick.

The seeds should in general be sown and covered in directly, if the ground is dry and in good order; but if the soil is wet, especially at an early season, it may be proper to suffer the drills to lie open exposed to the sun and air an hour or two, or more, to dry a little, particularly for tender seeds in early sowings, in the full ground. The sowing in the drills is performed for the most part with a locked or close hand, discharging the seeds from between the fore-finger and thumb, scattering them evenly along the bottom of the drill, some sorts requiring to be sown thinly just along the middle, such as in the angular drills drawn corner-ways of the hoe, for peas and many other larger seeds; also sometimes for smaller seeds when intended for edgings; but in the shallow flat-bottomed drills, it is generally intended for the seeds to be scattered evenly the whole width of the drill, thicker or thinner, according to the nature of growth of their respective plants.

The work of covering or turning in the earth in the drills over the seeds, may be performed occasionally both with the rake, hoe, and feet; but the rake or hoe is the most proper for general practice for all smaller seeds, drawing the earth evenly into the drills a regular depth fully to the depth of the drill, whether deep or shallow: however, peas, beans, kidney-beans, and such-like larger seeds in large drills at wide distances, are often covered in with the feet, by slipping them lightly along each side of the drill alternately, turning the earth evenly in over the seeds; the surface being then lightly trimmed along with the rake, to smooth it and clear off large stones, &c.

In the last method, the ground being dug and formed into four or five feet-wide beds, with alleys a spade's width or more between bed and bed, and the earth drawn off the top of the bed with a rake or spade half an inch or an inch or more deep into the alley, the seed is sown all over the surface of the bed; which done, the earth in the alley is immediately, either with a rake, drawn spreadingly upon the bed again over the seeds the same depth, or spread over with a spade, and the surface raked smooth and even in a similar manner.

It is often practised in the nurseries, especially in sowing some large sorts of seeds, as well as others, but not very frequently in kitchen-gardens. It is not so expeditious as the Broad-cast sowing, but is very proper for many sorts of small seeds, and many sorts of the tree and shrub kind, being a very regular method of sowing so as to cover all the seeds an equal depth, and is performed two or three different ways; such as by the rake, by the spade, and by sifting.

It is also sometimes performed with the rake and spade together, particularly when intended to sow any large seeds a good depth, using the rake to shove or rake the earth from off the bed into the alleys; or if it cannot be conveniently performed with the rake a proper depth, it is effected with the spade, trimming or paring the earth evenly off the surface into the alleys; then sowing the seeds all over the surface; and if they are of the larger berry, nut, or stone kind, or any other large seed, previous to covering them, pressing or patting them all evenly down into the earth with the back of the spade; and then, either with the rake or spade, spreading the earth out of the alleys evenly over them; though if it is a deep covering, especially when taken off with the spade, it is most eligible to use the same implement in returning it, being careful to spread it evenly, to cover the seeds all equally a proper depth, smoothing the surface with the rake.

Another method sometimes practised with large seeds is, that when the ground is laid out in beds unraked, the seed is sown on the surface, and with a rake stricken a little into the earth; then with the spade paring the alley, and casting the earth evenly over the bed, half an inch, or an inch or more deep, as may be required, raking the surface even. This is also sometimes practised in wetish ground, at an early season, when it does not readily admit of treading or raking. And by deepening the alleys, and raising the beds, it drains the moisture from the surface.

The method by sifting is sometimes practised for several small or light seeds of a more delicate nature, that require a very light covering of earth when sown; as in order to cover them as shallow as possible, it is done by sifting fine earth over them out of a wire or chip sieve. Before the seed is sown, the surface of the bed, &c. is raked fine; then the earth thinly shoved off the surface of the bed with the back of the rake into the alley, making the surface as smooth as possible, and then sowing the seed, smoothing it down lightly with the spade, and sifting the earth in the alley evenly over it, to a suitable thickness, as half a quarter or a quarter of an inch deep; or sometimes the surface is only raked as smooth as possible, without drawing off the earth, or sometimes lightly smoothed with the back of the spade, then sowing the seed, and letting some loose fine earth from the alley, or some brought for the purpose, be sifted thinly over it.

The modes of sowing the different sorts of seed crops are more fully explained under their respective heads.

SPADE, an useful garden implement, used for digging and preparing the soil for the reception of all sorts of seeds and plants.

There are several sorts and sizes of spades occasionally employed, though the common large digging spade is, in most places, almost commonly used for all kinds of digging and spade-work, which, however, in many instances, cannot be so conveniently used as a middling or small spade; it is therefore eligible for every garden to be furnished with three different sizes of spades, to suit every department of gardening the more commodiously; such as the common Large digging Spade, for all common digging and spade-work; a Middling, and a Small Spade for digging particular narrow compartments, and between small plants closely placed in beds and borders, &c.

The first sort is usually from fourteen to fifteen inches long in the plate, and nine broad, narrowing gradually half an inch or an inch less at the bottom.

The second sort should be about a foot long in the plate, and seven or eight inches broad.

The Small Spade, which is about eight or nine inches long in the plate, and five wide, is convenient in pointing up or slight digging, and in fresh loosening the surface between close-placed small plants, in beds and borders, &c. where neither of the two former spades can be readily introduced: it is also useful in planting and potting many sorts of small plants, taking up small roots, and other light purposes.

And a very Small narrow Spade, having the plate about seven inches long, by three and a half or four wide, is also very useful in small compartments of beds, borders, &c. containing some particular close-placed, small plants of flowers, and others, both in occasionally slightly digging, or loosening the earth between them with greater care and effect, than a larger sized spade; also sometimes in similar compartments in occasionally trimming round the bottom part of some straggling fibrous-rooted plants; and it is also often useful in taking up and transplanting small plants, and taking off root off-sets and slips, in particular sorts, in which a larger spade would not be so convenient. And a Semicircular, or Scooped Spade, is another sort, of a smallish size, having the plate made hollow like a scooped garden-trowel, which is very useful in taking up small plants with balls of earth, to preserve the ball more firmly about the roots.

Proper Garden Spades have the plate wholly of iron, not above a quarter of an inch thick upward, growing gradually thinner from the middle downward; the tree or handle being generally of ash, about two feet long, and an inch and half thick, with a firm open handle at top, formed out of the solid wood, just big enough to admit of taking ready hold.

SPARTIUM, a genus containing plants of the deciduous and evergreen kinds.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved perianth, cordate-tubular: at the upper edge very short, below towards the tip marked with five toothlets, coloured, small: the corolla papilionaceous, five-celled: standard obcordate, the whole reflexed, very large: wings ovate, oblong, shorter than the standard, annexed to the filaments: keel two-petalled, lanceolate, oblong, longer than the wings, (the carinal margin connected by hairs,) inserted into the filaments: the stamina have ten connate filaments, adhering to the germ, unequal, gradually longer; the uppermost very short; the lower nine-cleft: anthers oblongish: the pistil-

lum is an oblong germ, hirsute: style awl-shaped, rising: stigma growing to the upper side of the top, oblong, villose: the pericarpium is a cylindric legume, long, obtuse, one-celled, two-valved: the seeds many, globe-kidney form.

The species cultivated are: 1. *S. scoparium*, Common Broom; 2. *S. junceum*, Spanish Broom; 3. *S. radiatum*, Starry Broom; 4. *S. monospermum*, White-flowered Single-seeded Broom; 5. *S. sphaerocarpum*, Yellow-flowered Single-seeded Broom; 6. *S. Scorpius*, Scorpion Broom; 7. *S. angulatum*, Angular-branched Broom; 8. *S. spinosum*, Prickly Broom.

The first grows from three to six feet high or more, very much branched; the branches upright, rushy, evergreen, angular, flexible, leafy, smooth except the very young ones which are downy; the leaves ternate, small, ovate, acute, downy and edged with soft hairs bending inwards; the leaf-stalks are also slightly hairy, and flattened: the flowers axillary, solitary or two together, rarely three, nodding, on round smooth peduncles, furnished on each side with a very minute stipule, of a fine yellow colour. It is a native of Europe, flowering in May and June.

There are several varieties, some of which merit a place among flowering shrubs; as that with a purple calyx, and the flowers strongly tinged with orange, as well as that which is very hoary.

The second species has the branches smooth, flexible, eight or ten feet high; the lower ones have small smooth leaves, at the end of the shoots of the same year; the flowers are disposed in a loose spike, are large, yellow, have a strong agreeable odour, appear in July, and in cool seasons continue in succession till September. It is a native of all the Southern countries of Europe.

There is a variety with double flowers.

The third has low stems, with opposite four-cornered branches: the leaves opposite, subsessile: leaflets sessile, thin, subpubescent: the petioles extremely short, but permanent, three-cornered, gibbous, very blunt, thicker than the branchlet to be supported: the flowers terminating, in threes, sessile. In its natural state it is a low shrub; when cultivated it becomes much larger, though rarely exceeding two feet and a half in height, but the branches spread very much and form a large bush; they are angular and pliable, and always come out by pairs opposite: the leaves narrow and awl-shaped, placed round the stalk, spreading out like the points of a star: the flowers in small spikes at the end of the branches, bright yellow, but not

more than half the size of the second sort, and without scent. It flowers in June, and is a native of Italy.

The fourth species has a thick stalk, covered with a rugged bark when old; it rises eight or nine feet high, sending out many slender rush-like branches of a silvery colour, almost taper, which terminate in very slender bending ends; these have a few narrow spear-shaped leaves on the lower branches: the flowers are produced in very short spikes or clusters on the side of the branches; are small and white. It is a native of Spain and Portugal, flowering in June and July.

The fifth has an upright stem: the branches numerous, slender, round, smooth, slightly striated, having a few tubercles scattered over them, below leafless: the leaves on the younger branchlets small, lanceolate, deciduous, silky, with very short hairs pressed close: the flowers small, racemed, each on a very short pedicel. It is a native of the South of Europe and Barbary, flowering in June and July.

The sixth species is a shrub wholly covered with alternate spines, on which the flowers are placed; this renders it quite inaccessible: the branches and leaves are striated and ash-coloured, and the latter are a little villose: the flowers are yellow and rather large. It is a native of the South of Europe and Barbary, flowering in March and April.

The seventh has the stalks and branches slender, having a few trifoliate and single leaves towards the bottom: the branches have six angles or furrows: the flowers small, of a pale yellow colour, produced in loose spikes at the ends of the branches, rarely producing seeds in this climate. It is a native of the Levant.

The eighth species has stalks five or six feet high, sending out many flexible branches, armed with long spines: flowers terminating in clusters, each upon a long pedicel: corolla bright yellow, appearing in June. It is a native of Italy and Spain.

Culture.—The three first sorts are hardy, but the others more tender, especially in their young growth.

They are all capable of being raised from seeds, and the double-blossomed sorts by layers and cuttings. The seeds should be sown in the early spring, as about April; the hardy sorts in beds of common earth, either in drills or by bedding in to the depth of an inch: but in the tender sorts in pots or beds hooped over to protect them in frosty weather. In the following spring they should be removed into nursery-rows or larger pots, according to the kinds, shortening their tap-roots, and setting them out in rows two feet

Vol. II.

apart, at the distance of one in the rows, to remain two or three years, when they may be planted out in the shrubbery, or other places: the tender sorts in pots being removed to the greenhouse or garden for protection in winter, being managed as the hardy sorts of plants of this kind.

The layers should be laid down in the autumn or spring, and the cuttings may be planted out in the spring or summer, some in the open ground, and others in pots plunged in the hot-bed to promote their striking root. They may be managed afterwards as the other sorts.

This is the only certain mode of preserving the varieties.

The hardy sorts are very ornamental in the borders, clumps, and other parts, and the tender kinds in greenhouse collections, and among other more hardy potted plants.

SPAWN, the progeny or offspring of plants or other vegetables; but it is mostly applied to such small offsets, suckers, and sprouts as rise numerously from the roots, &c. of certain plants, serving for the purpose of increase, which, as being parts similar to the whole plant, when separated from the parent vegetable and planted out, readily grow, and commence proper plants, and thereby renew or increase their respective kinds with great facility and abundance.

In a general acceptation, it is, however, more peculiarly applied to the progeny of mushrooms, being an offspring from the root of those fungi, consisting of minute white parts, shooting and running in the earth or dung, like small white thready fibres, assuming the appearance of slender white strings, which are productive of numerous minute white knobs, appearing at first the size of small pin-heads, the whole smelling strong of the mushroom; and those little knobs being infant plants, they gradually increase in size to proper mushrooms, which are quick of growth, and of very short duration; but the same spawn running in the earth, &c. furnishes a plentiful supply of mushrooms from the bottom in regular succession for a considerable time, sometimes several months. See **AGARICUS**.

It may be procured at all seasons of the year, but more plentifully towards the end of summer and in autumn, from the places of its growth; such as old mushroom beds, old horse-dung hot-beds, and horse-dunghills that are moderately dry, and which have remained undisturbed several months; also sometimes in old compost heaps, consisting chiefly of horse-dung; in all of which the spawny substance discovers itself in dry lumps of dung and earth, which lumps should be taken up entire: likewise in stable-yards, where any quantity of horse-dung has lain dry

and undisturbed any considerable time, lumps of spawn are often obtained. It is also found in fine perfection in the horse-rides belonging to great inns, livery-stables, and horse-dealers, especially on the sides next the walls: likewise in horse-mill tracks, where horses are constantly employed in working; also in kitchen-gardens, where any piece of ground has been dunged in the spring, with new, or but moderately-rotted stable-dung, or old dry hot-bed dung, &c.

And sometimes it is produced naturally all over the surface of an old cucumber or melon hot-bed, both in the dung and earth, in autumn or winter, where the frame and lights have been continued over the bed; and where the earth of the bed is of a loamy nature, the spawn is often remarkably fine and strong; for in this kind of earth, of a moderately-light quality, it is generally of a superior quality, and very productive; so as sometimes, in such old beds where the frames and glasses remain, and the surface of the bed is covered thickly with dry straw, litter, or hay, under the glasses, to produce a full crop of good mushrooms towards the spring. See AGARICUS.

Mushroom spawn is also obtained in meadows and pastures towards the end of summer and in autumn, before the rain and cold commences; as in the months of August and September, when the mushrooms rise naturally, serving as a direction to the place where to find it; but that found in the other places is mostly the best.

It is necessary to observe, that there is also a fruitful and barren sort of mushroom spawn; the former is distinguished by the substance of the fibry or stringy white shoots, &c. and mushroom-like smell, as before observed; but in the latter sort, the thready fibres are far more abundant, fine, and downy, often appearing like a fine white down, and, being of no substance, produce only a flash of small white fungi destitute of the fleshy part, and which, by the mushroom-men, is commonly called White-cup.

Methods are sometimes practised to obtain mushroom spawn more abundantly by art, by the effects of horse-dung, both in hot-beds and in compost heaps; sometimes, in the former case, by planting small pieces of spawn, or spawny earth, along the top edge of the later cucumber hot-beds in summer, or in the sides of any horse-dung heaps, having a little warmth remaining; so that the moderate heat of the dung in the bed or heap may set the spawn a-running, so as sometimes to produce a few mushrooms in autumn, and increase it considerably for future use in spawning proper mushroom beds: and in the second case, by a compost of

dung and loamy earth together; procuring in spring, or early in summer, a quantity of fresh horse-dung, consisting of plenty of short stuff, and a due proportion of long; and casting the whole into a heap to ferment a fortnight or a month, that the rank burning vapour may pass away; then having some loamy earth, or other good substantial mould, or any spawny soil from old beds, form the dung into a long narrow ridge, mixing some of the earth occasionally towards the outside; and in a fortnight or three weeks, when the heat becomes quite moderate, covering the whole with dry long litter to defend it from the wet, permitting the whole to remain a considerable time, when good spawn will often be produced.

In collecting it from any of these places, the lumps of dung and earth in which it appears should be taken up as entire as possible, put in a basket, and carried into some dry shed, or other place, till wanted, or it may be immediately used.

SPEARAGE. See ASPARAGUS.

SPEAR-KING'S. See ASPHODELUS.

SPEARMINT. See MENTHA.

SPERAGE. See ASPARAGUS.

SPERMACE, a genus containing plants of the herbaceous, annual, and shrubby kinds.

It belongs to the class and order *Tetrandria Monogynia*, and ranks in the natural order of *Stellatæ*.

The characters are: that the calyx is a small four-toothed perianth, superior, permanent: the corolla one-petalled, funnel-shaped: tube cylindrical, slender, longer than the calyx: border four-parted, from spreading reflexed, obtuse: the stamina have four awl-shaped filaments, shorter than the corolla, or standing out: anthers simple: the pistillum is a roundish germ, compressed, inferior: style simple, but cloven above: stigmas obtuse: the pericarpium has two capsules, connate, oblong, gibbous on one side, flat on the other, obtuse; each two-horned: the seeds solitary, roundish.

The species cultivated are: 1. *S. tenuior*, Slender Button-weed; 2. *S. verticillata*, Whorl-flowered Button-weed.

The first grows to the height of two feet and a half: the stalks are stiff, a little angular, and covered with a brown bark; the branches come out by pairs: there are two leaves at each joint placed opposite, two inches long, and almost a quarter of an inch broad; between these come out three or four smaller leaves, which stand in whorls round the stalks; they are smooth, and have one strong nerve or rib in the middle: the flowers grow in slender whorls toward the top of the stalks; are small, white, and sessile,

having a whorl of leaves close under them. It is a native of Carolina and the West Indies, flowering in June.

The second species has a shrubby stem, three or four feet high, sending out a few slender branches, with narrow leaves on them, not so long as those on the first sort; they are smooth, of a light green, and stand in a kind of whorl round the stems, two being larger than the others in each whorl: the flowers grow in thick globular whorls towards the top, and one terminates the stem; they are small and very white. It is a native of Jamaica and Africa, flowering here from June to August.

Culture.—These plants are increased by sowing the seeds on a moderate hot-bed early in the spring, or in pots to be plunged in it: when the plants have attained some growth, they should be removed into separate pots filled with good friable mould, replunging them in the bed.

They should afterwards be managed as other plants of the exotic stove kind.

They afford variety in stove collections.

SPINACIA, a genus containing a plant of the annual culinary kind.

It belongs to the class and order *Dioecia Pentandria*, and ranks in the natural order of *Holotraceæ*.

The characters are: that in the male the calyx is a five-parted perianth: segments concave, oblong, obtuse: there is no corolla: the stamina have five capillary filaments, longer than the calyx: anthers oblong, twin:—female, the calyx is a one-leaved perianth, four-cleft, acute, with two opposite segments very small, permanent: there is no corolla: the pistillum is a round compressed germ: styles four, capillary: stigmas simple: there is no pericarpium: calyx unites and hardens: the seed one, roundish, covered by the calyx.

The species is *S. oleracea*, Garden Spinach.

It has an annual root: the leaves sagittate: the stem hollow, branching, herbaceous, about two feet high: the male flowers are herbaceous, in long spikes; they abound in pollen, which, when ripe, flies out when the plants are shaken, and spreads all round; after which the plants soon decay: the female flowers, which are on a separate plant, sit in clusters close to the stalks at every joint; they are small, herbaceous, and are succeeded by roundish seeds, which in the prickly variety are armed with short acute spines. Its native place is not known.

There are varieties of this, which differ in the size and shape of the leaves, and the more or less prickliness of the seeds;—as the Triangular with prickly seeds: the Round with smooth seeds, which has ovate thick leaves, not angular at

their base; both stalks and leaves are much more fleshy and succulent; and the seeds are smooth without any spines. Of this also there are two or three subvarieties, differing in the shape, thickness, and size of their leaves.

Culture.—In these plants it is effected only by seed, by sowing it every year in spring and autumn; the former furnishing the main spring and summer crops; and the latter the winter, and for early spring use.

The Prickly sort is the best for winter crops, and the Round for the summer ones.

It should be sown at several intervals of time, from January till August, as every month, three weeks, or fortnight, according to the earliness or advanced period of the season, so as to obtain a regular succession most part of the year.

The general spring crop should be sown in March, and the general winter crop about the beginning of August.

In the spring sowings, as the crops in the very early sowings in January run soon to seed, a moderate quantity should only be sown.

But in the autumn sowings, as the plants do not run the same year, good full crops, to stand for winter and early spring use, should be put in.

It succeeds in any common soil of the kitchen-garden; but the richer in dung the better; always choosing an open situation, not too near low spreading trees, &c., as it never succeeds in close or shady places, in which it is always drawn up weak, and soon runs to seed, without attaining perfection: a warm border may be proper for the early crops; but for the main crops in general, the open quarters are the most suitable, though a broad warm-lying border may also be proper for some part of the later sown winter-crops occasionally, for the purpose of having the advantage of a little shelter of the fence, and benefit of the sun during the winter season; and fresh seed should be procured for each sowing; as this will be found of great importance in the free growth of the plants: for the autumn sowings of the winter crops, it is of advantage to procure new seed of the same year.

After the ground has been dug, the seed may either be sown broad-cast, and raked in, or in shallow drills a foot asunder; though broadcast is the most expeditious, and probably the most proper method for the growth of the crops, in the product of large full leaves; sowing it all over the surface moderately thin, either in one continued plat, and trodden down evenly, if light ground, and raked in with a large rake or light harrow; or the ground may be divided into four- or five-feet-wide beds, with foot-wide alleys between; especially for the early and winter

crops in moist ground; the seeds being sown as above, raking them in evenly: drill-sowing may also be occasionally practised, drawing the drills with a hoe flatways, near an inch deep, and ten or twelve inches asunder, scattering the seeds thinly along them, raking the earth over, full half an inch deep; which mode is very proper in sowing between other crops, as between wide rows of beans, peas, cabbages, &c. as it admits of hoeing up the weeds between the rows with facility; and if sown thin, and the plants be thinned properly, they grow large and fine, and the produce is very conveniently gathered. It may likewise be sown in wide drills alone, about a foot distance for a distinct full crop: or in rows two feet asunder, to admit of intercropping in the intervals with rows of cabbages, beans, and other things occasionally.

In these sowings the seeds should be scattered moderately thin, and the plants be thinned out to three inches distance at least, being directly raked regularly in: and when sown broad-cast all over the surface, if in light loose land, and a dry warm season in the advanced part of spring, or in the summer and autumn, it may be proper first to tread the seed evenly down, then raking it in effectually with a large rake.

The seeds mostly come up in a fortnight; or perhaps, if sown very early in spring, three weeks or a month.

In respect to the after-culture of the crops, when the plants have three or four leaves an inch broad they should be thinned and cleared from weeds, either by hoe or hand; but the former is the most eligible, especially for the broad-cast-sown crops; choosing dry weather, and cutting out the plants to three or four inches distance, together with all the weeds in every part; but the above distance is scarcely sufficient, unless intended to begin thinning out the plants for use while young: in other cases it is advisable to hoe them out six or eight inches asunder, especially the spring and summer crops of the Round Spinach, which, having proper room, will grow very large, and spread its broad leaves widely, and does not run to seed so soon as if left close. When the spring- and summer-sown crops are left too close, they are apt to draw up weak, and soon go to seed. The winter crops of Triangular or Prickly Spinach, when thinned out finally to three or four inches distance, will be sufficient.

These crops are often sown in spring with other crops, for the sake of cropping the ground to the best advantage; but it is best alone.

When the plants have leaves two or three inches broad, they may be gathered.

The method of which is, either by cutting up

with a knife, wholly to the bottom, or cleaning out by the root if the crop wants thinning; or only cropping the large outer leaves; the root and heart, remaining, shoot out again. With the spring crops, when the plants want thinning, they may be cut up wholly to the root, thinning them out where thickest in a gradual manner, so as to leave the standing plants at least six or eight inches distant to grow to perfection, which, when beginning to shoot for seed, may also be cut up wholly to the bottom: and in the winter-crops, if the plants stand too close at first, some may be thinned out quite to the bottom, afterwards the larger outer leaves must only be cropped in the winter, and early part of the spring; but when the spring is more advanced, and the plants grown large and require thinning, or when they begin to run to seed, cutting them up to the bottom in a thinning order.

Some of the best of the different sorts of plants should be left in the spring to stand for seed, which should be collected when well ripened.

SPIRÆA, a genus containing plants of the shrubby and herbaceous kinds.

It belongs to the class and order *Icosandria Pentagynia*, and ranks in the natural order of *Pomaceæ*.

The characters are: that the calyx is a one-leaved five-cleft perianth, flat at the base, with acute segments; permanent: the corolla has five petals, inserted into the calyx, oblong-rounded: the stamina have more than twenty filaments, filiform, shorter than the corolla, inserted into the calyx: anthers roundish: the pistillum has five or more germs: styles as many, filiform, length of the stamens: stigmas headed: the pericarpium is an oblong capsule, acuminate, compressed, two-valved: the seeds few, acuminate, small, fastened to the internal suture.

The species cultivated are: 1. *S. salicifolia*, Willow-leaved Spiræa; 2. *S. tomentosa*, Scarlet Spiræa; 3. *S. hypericifolia*, Hypericum-leaved Spiræa; 4. *S. argentea*, Silvery-leaved Spiræa; 5. *S. chamaedrifolia*, Germander-leaved Spiræa; 6. *S. crenata*, Hawthorn-leaved Spiræa; 7. *S. triloba*, Three-lobed-leaved Spiræa; 8. *S. opulifolia*, Currant-leaved Spiræa; 9. *S. sorbifolia*, Service-leaved Spiræa; 10. *S. Aruncus*, Goat's-beard Spiræa; 11. *S. filipendula*, Common Dropwort; 12. *S. ulmaria*, Common Meadow Sweet; 13. *S. trifoliata*, Three-leaved Spiræa.

The first has the stalks very taper, and rough towards the top, and covered with a reddish bark: the leaves about three inches long, and an inch broad in the middle, bluntly serrate,

2 *Sisyrinchium iridioides*
Iris-leaved Sisyrinchium

and of a bright green colour. In rich moist ground the stalks rise five or six feet high, but in moderate land from three to four; as their whole height is one year's growth from the root: they are terminated by spikes of pale red or flesh-coloured flowers. It flowers in June and July; and in moist seasons there are frequently young shoots from the root which flower in autumn. It is a native of Siberia.

There are several varieties: as the Flesh-coloured Willow-leaved, the Alpine Willow-leaved, the Panicked Willow-leaved, and the Broad Willow-leaved *Spiræa*.

The second species has the stalks slender, and branching out near the ground, with a purple bark covered with a gray mealy down: the leaves smaller than those of the first, downy and veined on their under side, but of a bright green above: the branches terminated by a thick raceme of flowers, branched towards the bottom into small spikes: the flowers very small, of a beautiful red colour, appearing in July, August, and September. It is a native of Pennsylvania.

The third rises with several slender shrubby stalks five or six feet high, covered with a dark brown bark, sending out small side branches the whole length: the leaves small, wedge-shaped, having many punctures on their surface: the flowers in small sessile umbels, each on a long slender pedicel, and white: they appear in May and June; and as the flowers are produced almost the whole length of the branches, it makes a good appearance during the time of flowering. It is a native of Italy and America.

The fourth species has striated erect branches, with short branchlets: the leaves alternate, petioled, silky-tomentose on both sides: the racemes longer than the branchlets: the flowers very small, with villose germs. It is a native of New Granada.

The fifth has abundant shoots, seldom two ells high, the thickness of the finger, wand-like, branched: the wood brittle: the bark of the shoots yellowish-brown, with prominent dots scattered over it: the branches alternate, commonly angular, with a testaceous bark somewhat striated, and in the younger branches covered with a tender ash-coloured epidermis, which falls off; the annual shoots are grooved and pubescent: the leaves alternate, softish, pubescent with prostrate hairs, quite entire at the base, but commonly gash-serrate from the middle to the end, where they are sharp: corymbs at the top of the stems frequent, many-flowered, terminating the annual alternate shoots: in gardens and in moist shady places these corymbs are more elongated; but in a ruder soil most of the peduncles are clustered at the top

like an umbel: the flowers biggish, white, having a weak virose smell, and fugacious. It is a native of Siberia, &c.

It varies very much, with larger or smaller leaves, more or less cut, but more commonly quite entire and ovate-acute.

The sixth species has several stems, scarcely two ells high, very much branched from the bottom: the branches rod-like, round, with a testaceous bark cloven longitudinally: the leaves on the younger branches and annual shoots alternate, attended with smaller ones in little bundles, hoary or glaucous, three-nerved, hardish, varying in form and size; on the luxuriant shoots or branches sometimes ovate-acute, widish, serrulate from the tip beyond the middle; but commonly oblong, bluntish, crenulate, or serrulate towards the tip, or more commonly quite entire: the corymbs at the ends of the annual twigs, very abundant, disposed along the branches on one side, in hemispherical clusters: the flowers smallish, white, odorous. It is a native of Spain, &c., flowering here in April and May.

The seventh has numerous stems, scarcely thicker than a swan's quill, very much branched, upright, with a gray bark more or less pale, and somewhat angular, with sharp streaks running down from the branches: the branches and branchlets alternate, those of the last year very smooth and yellow, leafy, and terminated by an umbel: the leaves alternate, on very short petioles, smooth, glaucous, wide-ovate, retuse, gash-trilobate: they vary even in the garden, with fewer or more frequent gashes, with the teeth or lobes obtuse or acute, in breadth, &c.: the umbels very frequent at the ends of the annual branches: peduncles often more than thirty, besides a few axillary ones scattered below the umbel: the flowers middle-sized, white. It is an elegant shrub, and a native of Siberia.

The eighth species rises with many shrubby branching stalks, eight or ten feet high in good ground, but generally five or six; they are covered with a loose brown bark which falls off: the leaves about the size and shape of those of the common currant bush, ending in acute points, and serrate on their edges: the flowers are produced in roundish bunches at the end of the branches; are white with some spots of a pale red. It is a native of Canada and Virginia. It is commonly known in the nurseries by the name of Virginian Gelder Rose.

The ninth rises with shrubby stalks like the first, but sends out horizontal branches, which are slender, and covered with a brown bark: the leaves are of a thin texture, and a bright green colour on both sides, slightly and acutely serrate: the flowers in terminating panicles, small

and white. It is a native of Siberia, flowering in August.

The tenth species has a perennial root: the stem annual, from three to four feet high: the leaves doubly pinnate; each having three or four pairs of oblong leaflets terminated by an odd one: they are two inches long, and almost an inch broad, serrate, and ending in acute points: the flowers disposed in long slender spikes, formed into loose terminating panicles; they are small, white, and of two sexes in the same spike. It is a native of Germany, flowering in June and July.

The eleventh has a perennial root, consisting of oval tubers or solid lumps, hanging from the main body by threads, which has given occasion to its common names, *Filipendula* and *Dropwort*. These tubers enable the herb to resist drought, and render it very difficult to be eradicated: the stem is erect, from a foot to a foot and half in height, angular, smooth, leafy, a little branched at top: the leaves alternate, interruptedly pinnate, serrate, and jagged, smooth, composed of several pairs of leaflets, all of each set uniform or nearly corresponding in size; the terminating leaflet three-lobed: a pair of roundish united indented stipules at the base of each leaf, embracing the stem: the flowers many in a cymose loose erect panicle, cream-coloured often tipped with red, or red on the outside. It is an elegant plant, which in gardens grows very luxuriant, and has often double flowers. It flowers early in July.

The twelfth has a perennial fibrous root: the stems erect, three or four feet high, angular and furrowed, tinged with red, leafy, branched in the upper part: the leaves interruptedly pinnate: leaflets very unequal in size, sharply serrate, clothed beneath with white down, the end one remarkably large and three-lobed: a pair of rounded serrate stipules are joined to the common leaf-stalk, and clasp the stem: the flowers white, in a large very compound cyme, the side-branches of which rise much above the central one: it perfumes the air with the sweet hawthorn-like scent of its plentiful blossoms from June to August.

There are varieties with double flowers, and with variegated leaves.

The thirteenth has a perennial root: the stalks annual, about a foot high, sending out branches from the side the whole length: the leaves for the most part trifoliate, but sometimes single or in pairs; they are about an inch and half long, and half an inch broad, ending in acute points, sharply serrate, of a bright green above, and pale beneath: the flowers in loose terminating panicles, on slender peduncles. It

is a native of North America, flowering in June and July.

Culture.—In all the shrubby sorts, this may be performed by suckers, layers, and cuttings.

The suckers should be taken off in the autumn and planted out where they are to remain, or in nursery-rows, to attain a fuller growth.

The first sort requires to be cleared of these suckers every two years at furthest.

The layers should be put down in the autumn or in the spring, and may be taken off and planted as above, in the autumn or spring following: all the sorts may be raised in this way; but it is most proper for such sorts as do not send off suckers.

The cuttings may be made from the shoots of the preceding summer, and be planted out in a shade border in the early autumn: when they have become well rooted they may be removed and managed as the others: they succeed in this way with more difficulty than in either of the others.

All the herbaceous sorts may be increased by seeds, or parting the roots.

The seed may be sown in the autumn or early in the spring; but the first is the better mode, on a bed of fine mould: when the plants appear they should be kept clear from weeds till the autumn, when they may be planted out where they are to remain, or in the nursery for a year or two.

The roots should be parted in the autumn or spring, when the stems decay, before they shoot out new ones, being planted immediately where they are to grow.

The double-flowered and stiped varieties can only be preserved in this way.

They all afford variety and ornament in the shrubbery and other parts.

SPONDIAS, a genus containing plants of the exotic tree kind.

It belongs to the class and order *Decandria Pentagynia*, and ranks in the natural order of *Terebinthaceæ*.

The characters are: that the calyx is a one-leaved perianth, subcampanulate, small, five-cleft, coloured, deciduous: the corolla has five oblong petals, flat, spreading: the stamina have ten awl-shaped filaments, erect, shorter than the corolla, alternately longer: anthers oblong: the pistillum is an ovate germ: styles five, short, distant, erect: stigmas obtuse: the pericarpium is an oblong drupe, large, marked with five dots from the falling of the styles; ten-valved: the seed is an ovate nut, woody, fibrous, five-cornered; five-celled; covered with a fleshy elastic aril.

The species is *S. Mombin*, Purple Hog-Plum, or Spanish Plum.

Its usual height in its native situation is ten or twelve feet, and the stem is as large as a man's leg, sending out branches towards the top covered with a gray bark; these are destitute of leaves for some months; and in the spring, before the leaves appear, many purple flowers come out from the side of the branches; these are succeeded by fruit like plums, having a luscious thin pulp, covering a large fibrous stone: the leaves which come out afterwards are unequally pinnate, with four or five pairs of leaflets, about an inch long and half an inch broad. It is a native of South America.

It is cultivated in its native state by many for the sake of the fruit, which is pretty pleasant.

There is a variety of this fruit called The Leathercoat, from the appearance of its skin.

Culture.—It is increased by sowing the stones of the fruit in pots filled with light mould, plunging them in the bark-bed of the stove; and by planting, cutting, or putting down layers, and managing them in the same way: the plants may be taken off and removed into separate pots when they have stricken good roots, being replanted in the bark-bed.

They require afterwards to be kept constantly in the stove, and to have the same management as other woody exotics of the same nature.

They afford variety in stove collections.

SPROUTS, the small young shoots or suckers emitted from the sides of the stems and heads, of vegetables, being in many instances a sort of compendium of the plant that produced them; and, when detached and planted, although destitute of roots, often emit fibres, shoot at top to mature growth, and exhibit leaves, flowers, and seed, as the parent plant.

In some herbaceous esculent plants, the young sprouts are excellent eating; as in the cabbage kinds, &c. affording a very profitable after-crop: the sprouts produced from the forward cabbage-stalks in summer and autumn are always larger and finer than the winter and spring sprouts; and sometimes the sprouts produced on the stalks of the early-cut cabbages often also cabbage into tolerable little firm heads towards autumn; in the Sugar-loaf Cabbage particularly, and other

forward kinds; producing abundance of fine sprouts in summer, which, being gathered while young and green, constitute some of the most excellent culinary greens of the season; likewise forward Savoys being cut early in autumn, the remaining stalks produce fine large sprouts the same year, fit for use in the early part of winter; later crops of the same plants produce also abundance of small sprouts in the spring; and the Borecole is remarkable for its great production of sprouts towards spring, emitted all along the small stems from the very bottom to top; also Purple Brocoli never fails to produce a secondary crop of excellent sprouts furnished with little tender heads.

In the culture of all the varieties of the cabbage kind, it is proper, therefore, after gathering the main-heads, to leave a quantity of the stalks of the best and more forward crops, of the respective sorts, to produce sprouts; and if, towards autumn or winter, &c., the ground should be wanted for other crops, the stalks may be removed and trenched in by the roots in another place, not in any shady by corner, as often practised, nor placed too close, as the sprouts would prove small and trifling, and be liable to be eaten up by slugs; but in an open situation, in rows a foot asunder, in which method the sprouts will continue their growth in much greater perfection, though probably not in so good as if the stalks had remained undisturbed.

As the stalks of Cauliflowers and Cauliflower-brocoli rarely produce any sprouts, it is needless to leave them standing on the ground.

STANDARD TREES, such as stand singly with an upright stem without being trained to any wall or other support. The term is applicable to all sorts of fruit- and forest-trees, as well as other tree and shrub kinds that have upright stems, and which stand detached erectly without support; though it is more generally understood of such trees as grow with tall erect stems, six or eight feet high or more, before they branch out to form the head; such as the common apple-, pear-, and other fruit-trees in orchards and gardens, and the common forest-trees of the woods and fields. In gardening, they are distinguished into three sorts; as Full Standards, Half Standards, and Dwarf Standards; from their being occasionally trained in all these ways: but forest and tall-ornamental trees rarely in any other than Full Standards; though, in the shrub tribe, they are occasionally formed both into Half and Dwarf Standards, according to their natural growths.

Full Standards.—These are such trees as are trained with tall, straight, clean stems, six or seven feet high or more, then suffered to branch

out at that height all around to form a head, as in common standard apple- and pear-trees, forest-trees, &c.

Such trees as are designed for full-standards, should be trained accordingly in their minor growth, by trimming off all lower lateral branches gradually as the stem advances in height, to encourage a clean straight growth to the proper height, and promote the aspiring of the top or leading shoot more expeditiously; suffering the leader always to remain entire, especially in all forest-trees; or, if it should happen to fork, taking off the worst, and leaving the straightest shoot to run up, to continue the prolongation of the stem; and having thus run them up with clean stems gradually from six or seven to eight or ten feet or more, especially the deciduous kinds, suffer them to branch out into a full head, and run in height as fast as possible; though in fruit-trees the stem is often topped at six or seven feet height, to force out a set of laterals in that part, to form a regular spreading head of but moderate height, for the greater convenience of gathering the fruit; but for all kinds of forest-tree standards the tops should never be reduced, but the leader be permitted to remain entire to run up in height; as the beauty and worth of such trees consist in their lofty growth.

But in several forest and ornamental standards of the evergreen tribe, the trimming their stems from laterals while young, in this way, must be but sparingly practised; such as the pines, firs, cedars, and several others, which, being of a resinous nature, do not succeed if too closely pruned; besides, when designed for ornamental plantations, the trimming up the under branches would greatly diminish the beauty of their peculiar growth; for the disposition of the branches in most of them, covering the stem in circular rays to the very bottom, is thought additionally ornamental. The lower disorderly stragglers should of course only be taken off.

Most sorts of fruit-trees may be trained for full standards, except vines; though some of them will not ripen their fruit effectually in this way, as peaches, nectarines, apricots, and figs; but, on the other hand, all sorts of apples, pears, plums, and cherries, ripen their fruit freely on standards.

All fruit-trees for this purpose are raised by grafting, &c. on the freest strong-shooting stocks, and trained with straight clean stems, as above, either the stock trained up to that height, and then grafted or budded, the graft or bud branching out forming the head, or the stock grafted, near the ground, and the first shoot from the graft or bud trained up for a stem to the proper height, then suffered to send

forth branches; in either method, it is next to be considered whether it be intended the tree shall form a spreading open head, or assume a more erect and aspiring growth; in the former case, if the leading shoot of the graft or bud be topped at six or seven feet from the ground, it will force out lateral shoots at that height, and commence a spreading head open in the middle, suffering, however, the whole afterwards to take their own growth; and in the latter by permitting the leading shoot to remain entire, it will aspire in height, and the whole head will assume a more upright and lofty growth; in both methods the heads will afterwards naturally branch out abundantly, and furnish themselves sufficiently with bearing wood, producing fruit, in some sorts, in two or three years from the grafting and budding, as in cherries, apples, &c. but pears are sometimes four, five, or six years before they bear.

It is expedient to train most of the principal hardy fruit-trees as full standards, that, when planted in continued rows, either in gardens or orchards, by having tall stems, they may admit the influence of the sun and air more freely to the heads, and permit the obtaining crops of esculents, grass, &c. from the ground under them.

In respect to the management of full standard fruit-trees, little is required after the first training, to form the stem to the proper height, and the first shoots are advanced at top to give the head its first formation, being allowed to advance nearly in their natural order, except reducing any very irregular growths, permitting the whole to shoot both in length and branch laterally in their own way; by which they naturally form fruit-spurs along their sides upwards for bearing.

The irregular branches must, however, be removed, and the heads kept properly thinned, as well as the suckers rubbed off from the stems or other parts. See PRUNING.

Standard fruit-trees with high stems are sometimes planted against walls, and trained as wall-trees; this is practised for high walls, so as immediately to cover the upper parts of them, whilst Dwarfs and Half Standards cover the bottom and middle parts, and thus every part of the wall is fully occupied at once: but in these cases the dwarf-trees are to remain, the others being wholly destroyed after a time. See WALL-TREES.

These sorts of high standards are likewise occasionally placed against the ends of buildings; some choice sorts of pears in particular: also apricots in a southerly aspect, and other fruit-trees of the same kind.

Half Standards.—These are trees trained with stems only three or four feet high, then suffered

to branch out to form heads. It is practised for many sorts of fruit-trees, both as detached standards for variety, and with fanned spreading heads, as wall-trees for high walls.

The method of raising these is nearly the same as for the full standards; only they are grafted or budded upon lower stocks, training them with upright single stems only three or four feet high, by the stocks on which they are grafted being trained up to that height for a stem; or by being grafted or budded low in the stock, and the first main shoot of the graft, &c. led up for a stem, and topped at that height to force out branches to form the head; suffering the heads in those designed as detached standards, to branch out all around, and run up to a full spread, nearly according to their natural mode of growth, except just reforming any ill-growing branch, as shortening the branches should be sparingly practised, as it would force out numerous useless shoots, and prevent the formation of bearing wood, especially in the apple, pear, plum, and cherry kinds.

When Half Standards are intended for walls, they should have the head trained in a somewhat fanned manner, to spread to the wall like a common wall-tree.

When it is necessary to have them to form heads of as moderate growth as possible, especially in the detached half standards for small compartments, they should be grafted or budded upon the more dwarfish sort of stocks, as apples upon codlins, and pears upon quinces, &c.; in which case the heads will always shoot moderate, and never ramble wide or grow high. See STOCKS.

But though a few of this sort of trees may be eligible as detached half standards for variety, they are not proper for the open quarters of the garden; as their branches coming out low may impede the growth of under-crops.

For walls, however, that are eight or nine feet high, they are proper to plant between the dwarfs or principal residents, to cover the middle or upper half of the wall, whilst the dwarfs occupy the lower space. See WALL-TREES.

Half Standard cherries, apricots, &c. are also proper to plant in forcing-frames to produce early fruit. See FORCING-FRAMES.

The after-management of detached trees of this sort, in respect to pruning, is nearly the same as the full standards, as, after having shot out at top to form the head, they should be permitted to branch both in length and laterally nearly in their own way, except just pruning to order any considerable irregularity, crowding branches in the middle or long ramblers, and detaching all suckers from the root, stem, and

VOL. II.

head, and to cut out casual dead wood; and thus the regular branches remaining at length, will emit fruit-spurs abundantly in every part for bearing.

The Half Standards against walls are to be pruned and managed as other wall-trees, each according to its nature.

Dwarf Standards.—These are trained with low stems only one or two feet high, and then topped to force out branches to form the head.

Several sorts of choice fruit-trees are trained as dwarf standards, with stems not more than one foot high, branching out at that height, forming proportionably low heads; being occasionally planted round the borders of the kitchen- or pleasure-garden, &c., instead of espaliers, and the heads either kept down low by close pruning, or suffered to branch upward nearly in their natural growth. These are raised by grafting, &c. upon the most dwarfish stocks, such as apples on codlin- or paradise-stocks, and pears on quinces, &c. in order to dwarf them as much as possible in their growth; and as they shoot in height, each year's shoots either pruned short, to keep the head down and confine it within a small compass; or the branches permitted to shoot in length, except just reducing casual ramblers and disorderly growers. These kinds of dwarf standards are not so generally introduced now, as espalier fruit-trees have been brought to a proper degree of perfection in training and bearing.

Some have Dwarf Standard fruit-trees in pots, for the purpose of forcing in hot-houses, forcing-frames, hot-beds, &c. particularly early May and May-duke cherries, plums, peaches, nectarines, apricots, figs, vines, gooseberries, currants, &c. which being placed as above, in January or early in February, often ripen a few fruit very early in tolerable perfection, some of which might be brought to table growing on the trees in the pots. Dwarf Standard fruit-trees are also proper to plant fully in the borders in forcing-frames. See FORCING-FRAME, and DWARF-TREES.

The different varieties of currants and gooseberries may be trained with a single stem a foot or more high, and then permitted to branch out into a regular head, keeping the internal part always tolerably open, and the branches moderately thin; and shortening them but sparingly, particularly the gooseberry, by which dwarf shrubby plants are formed.

STAFF-TREE. See CELASTRUS.

STAG'S-HORN-TREE. See RHUS.

STAPELIA, a genus containing plants of the succulent perennial kind.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Contortæ*.

The characters are: that the calyx is a one-leaved perianth, five-cleft, acute, small, permanent: the corolla one-petalled, large, flat, thick, five-cleft beyond the middle: segments wide, flat, acuminate: nectary, five leaflets, spreading, linear, grooved, emarginate with a dagger point, opposite to the segments of the corolla: leaflets five others, fastened alternately with these a little higher to the tube of the filaments, and running along it, vertical, bifid: interior segment erect, with the summit bent outwards; outer segment straight, compressed: the stamina have five filaments, united into a short tube; each anther fastened internally to the base of each vertical leaflet of the nectary, and wider than it, incumbent on the stigma, short, two-lobed, two-celled, produced below on both sides into an earlet, contiguous at the margin to each of the neighbouring anthers as far as the tip, and ascending at the tip: pollen united into ten corpuscles, crescent-shaped, flattish, ascending obliquely into the cells of the anther, each on a very short pedicel, (with a transverse base, incumbent on the upper margin of the earlet,) fastened by pairs to five small twin coloured tubercles, placed on the apex of the earlets, and adhering to the angles of the stigma: the pistillum has two ovate germs, flat inwards: styles none: stigma common to both germs, large, placed on the tube of stamens, acutely five-cornered, flat above, obliquely truncate-excavated at the sides for the reception of the anthers: the pericarpium two follicles, long, awl-shaped, one-celled, one-valved; the seeds numerous, imbricate, compressed, crowned with a down: the receptacle free.

The species cultivated are: 1. *S. hirsuta*, Hairy Stapelia: 2. *S. variegata*, Variegated Stapelia.

The first has the root composed of many strong fibres, from which arise several stalks, which send out other branches of the same shape from their side, having indentures at each angle their whole length, the points of which are erect: the stalks or branches deep green, but the angles and points of the indentures inclining to brown, especially if the plants be exposed to the open air in summer. The flowers come out from the side of the stalks upon long fleshy peduncles: the petal is of a thick leathery substance; the inside variegated and hairy, and the borders of the segments closely furnished with long brown hairs: in the centre is the double starry nectarium, the points of which

are lacerated, and it is of a purple colour. It is a native of the Cape, flowering in June and July.

The second species has many branches the size of a man's finger, four or five inches long, having several protuberant indentures on their sides which spread open horizontally, and ending in acute points; these branches spread on the ground and emit roots from their joints; they are angular, and of a deep green colour in summer, but in winter change to purplish; they abound with a viscous juice of a nauseous taste: from the side of the branches towards the bottom comes out the peduncle, at one of the sinuses; it is short, and sustains one flower of a yellow colour spotted with purple; it is a native of Africa, flowering in June and July. There are others that may be cultivated.

Culture.—These sorts are readily increased by cuttings or slips of the young branches, which should be exposed a few days in a dry covered place to heal over the cut part, and be then planted in pots filled with light poor dry fresh sandy earth with lime rubbish, plunging them in the tan-bed of the stove, where they soon strike root; when they are well rooted they may be removed into separate pots, replunging them in the bed till fresh rooted, when they may be placed on the tops of the flues, or on shelves in the hot-house; they are also capable of being preserved in the green-house; they have a fine effect in their leafless watery appearance and the beauty of their flowers.

STAPHYLEA, a genus containing plants of the hardy deciduous flowering shrubby kind.

It belongs to the class and order *Pentandria Trigynia*, and ranks in the natural order of *Trihilatæ*.

The characters are: that the calyx is a five-parted perianth, concave, roundish, coloured, almost as big as the corolla: the corolla has five oblong petals, erect, like the calyx: nectary from the receptacle of the fructification, in the bottom of the flower, concave, pitcher-shaped: the stamina have five oblong filaments, erect, length of the calyx: anthers simple: the pistillum is a thickish germ, three-parted: styles three, simple, much longer than the stamens: stigmas obtuse, contiguous: the pericarpium has three capsules, inflated, flaccid, united longitudinally by a suture, opening inwards by the acuminate apex: the seeds two, bony, globular, with an oblique point and an orbicular excavation by the side of the apex.

The species are: 1. *S. pinnata*, Five-leaved Bladder-nut: 2. *S. trifolia*, Three-leaved Bladder-nut.

The first has several shrubby stalks arising

from the same root, and growing ten or twelve feet high, covered with a smooth bark, and dividing into several branches, which are soft and pithy: the leaves are composed of two pairs of ovate leaflets terminated by an odd one; these differ greatly in size, according to the strength and vigour of the shrub; some being more than two inches long, and an inch and half broad; but on old weak shrubs they are much smaller, are smooth, entire, and of a light-green colour, standing upon pretty long footstalks: the flowers come out upon long slender pendulous peduncles, from the axils of the stalks near their extremity, in oblong bunches: the petals are white, and expand in form of a rose: the flowers appear in May. It is a native of the South of Europe.

The second species has a more substantial stem than the first, the bark of the old branches and stalks is smooth and of a gray colour; that of the young ones of a light green and very smooth: the leaflets are ovate, ending in a point, and serrate on the edges; the largest three inches long and two broad; but in old plants they are not much more than half the size: the flowers are produced from the side of the branches in longer bunches than those of the former sort, but their peduncles are much shorter; the flowers are of a clearer white, and their petals are somewhat larger; as are also the bladder capsules. It is a native of North America.

Culture.—These plants may be increased by seeds, suckers, layers, and cuttings. The seeds should be sown as soon as they become ripe, in the autumn, in a bed of common earth, to the depth of an inch; they should be kept clear from weeds, and refreshed in dry weather with water frequently: in the following autumn or spring the large plants should be removed into nursery-rows, at two feet apart and one foot distant in the rows, to remain till of sufficient growth for the shrubbery; the suckers may be taken up in autumn or early in the spring, with root fibres to them, and planted in nursery lines in the above manner: the layers may be put down from the young branches being either slit or twisted, and when properly rooted in the following autumn be planted out in the nursery as above: the cuttings should be made from the lower parts of the young shoots of the preceding year, planting them in a shady border in the autumn, and watering them frequently during the spring and summer when the weather is dry; and when well rooted, in the autumn following, planting them out in nursery-rows as above, or where they are to remain: they afford ornament and variety in the shrubbery parts of pleasure-grounds.

STAR APPLE. See *CHRYSOPTILLUM*.

STAR FLOWER. See *ORNITHOGALUM*.

STAR HYACINTH. See *SCILLA*.

STAR OF BETHLEHEM. See *ORNITHOGALUM*.

STAR THISTLE. See *CENTAUREA*.

STATICE, a genus comprehending plants of the hardy, herbaceous and under-shrubby kinds.

It belongs to the class and order *Pentandria Pentagynia*, and ranks in the natural order of *Aggregata*.

The characters are: that the calyx is a common perianth, of a different structure in the several species: the perianth proper one-leafed, funnel-form: tube narrowed: border entire, plaited, scariose: the corolla funnel-form: petals five, united at the base, narrowed below, above wider, obtuse, spreading: the stamina have five awl-shaped filaments, shorter than the corolla, inserted into the corolla by their claws: anthers incumbent: the pistillum is a very minute germ: styles five, filiform, distant: stigmas acute: the pericarpium is an oblong capsule, somewhat cylindrical, membranaceous, five-cusped, one-celled, valveless: proper calyx contracted at the neck, expanded in the border, cherishing the capsule when the corolla withers: seed single, oblong, hanging from a long cord.

The species cultivated are: 1. *S. Armeria*, Thrift, or Sea Gilliflower: 2. *S. Limonium*, Sea Thrift, or Sea Lavender: 3. *S. cordata*, Heart-leaved Sea Lavender: 4. *S. reticulata*, Matted Sea Lavender: 5. *S. echinoides*, Rough-leaved Sea Lavender: 6. *S. speciosa*, Plantain-leaved Sea Lavender: 7. *S. tatarica*, Tartarian Sea Lavender: 8. *S. pectinata*, Triangular-stalked Sea Lavender: 9. *S. suffruticosa*, Narrow-leaved Shrubby Sea Lavender: 10. *S. monopetala*, Broad-leaved Shrubby Sea Lavender: 11. *S. ferulacea*, Cut-leaved Sea Lavender: 12. *S. sinuata*, Scallop-leaved Sea Lavender.

The first has a perennial woody root, bearing many thick tufts of lax, linear, channelled, smooth, entire leaves: the scape erect, simple, pubescent, varying much in height (from two to eight inches or even a foot), terminated by a globular head of many flowers, encompassed by a many-leaved involucre, the base of which is attached to a singular cylindrical membranous sheath, about an inch long, and investing the top of the scape, its lower end being loose and lacerated, so that it seems to have been torn off from the root, and carried up with the young growing stem: the calyx small, erect: the corolla rose-coloured or pink (varying to deep red, scarlet and white). It is a native of Europe and North America: it flowers from June to August.

There are several varieties: as with red flowers, with scarlet flowers, with white flowers. Great Thrift with red flowers, with white flowers; and Small Sea Pink, with flesh-coloured flowers.

The second species has scarcely any resemblance to lavender, and none of its aromatic quality; has a strong, perennial, woody root: it varies much as to luxuriance, being sometimes found with leaves scarcely an inch long, and not more than six or eight flowers in a panicle, and at other times much larger, with the flowers far more abundant, of a bright blue colour, which distinguish it at a distance: it is a beautiful plant. It is a native of Britain, flowering in July.

There are several varieties: as Common Great Sea Lavender; Great Late-flowering Sea Lavender; Olive-leaved Sea Lavender; Deep Blue-flowered Sea Lavender; and White-flowered Sea Lavender.

The third has the stalks naked, about six inches high: leaves wedge-shaped, emarginate at the end, and sometimes quite entire, rigid, running down into the petiole; varying in size, according to the soil: the flowers numerous, blue, imbricate, one-ranked, sometimes pale red, appearing in August, but never produce seeds in this climate. It grows naturally near the sea, about Marseilles, Leghorn, &c.

The fourth species has a strong root, woody and perennial, bearing thick tufts of small narrow obovate spatulate or wedge-shaped leaves, slightly pointed but not awned, and entire: the scapes prostrate, very much branched: the branches flexuose, matted and entangled with each other, having an ovate sharp membranous bracte at each divarication: many of the branches are barren, and those often reflexed, but not always: the flowers few together in simple terminating spikes or bundles, erect, each enveloped in three or four larger blunt bractes: the ribs of the calyx, and the petals, are of a bright purplish blue, which turns white in drying. It is a native of the South of France and Malta.

The fifth is an annual plant, (biennial) with long narrow leaves, which are set with rough tubercles; the stalks about eight inches high, dividing into two or three small branches, which are terminated by short reflexed spikes of pale blue flowers, coming out late in August, and seldom perfecting seeds in this climate: it is a native of the South of Europe and Barbary.

The sixth species has many radical leaves, oblong, smooth, curled, ending in a sharp point: the stems a foot high, branched, round, firmer than in the other species, sometimes winged, three or four spreading round the bottom, where there is abundance of very elegant flowers which

are larger than those of the second sort and white, forming a handsome silvery head.—It is a native of Russia, flowering in July and August.

The seventh has the leaves about four inches long, and three quarters of an inch broad in the middle, diminishing gradually to both ends: the stalks rise about five or six inches high, dividing into several spreading branches, which are again divided into smaller; these are terminated by spikes of pale-blue flowers ranged on one side the footstalk: the whole, when growing, being spread wide, has somewhat the appearance of an umbel of flowers, which come out in August, but never ripen seeds in this climate. It is a native of Russia, flowering in June.

The eighth species is a native of the Canary Islands, flowering in September and October.

The ninth is a native of Siberia, flowering most part of the summer.

The tenth species has a shrubby stalk about two feet high, dividing into several woody branches, which spread out on every side; the lower parts of these are closely furnished with gray leaves of a thick consistence: the branches are terminated by panicles of blue flowers, coming out singly at a distance from each other, having one funnel-shaped petal, with a long tube, and dividing into five spreading segments at top: it flowers from June till autumn, but never produces seeds in this climate. It is a native of Sicily.

The eleventh has round stems, somewhat woody, naked with alternate chaffs, panicled: the branchlets very much subdivided, in bundles, filiform, imbricate with very minute chaffs, terminated by a little bristle: the flowers subimbricate, ascending, directed one way, yellow. It is a native of Spain, of Portugal, and of Barbary.

The twelfth is a biennial plant: the lower leaves, which spread on the ground, are indented almost to the midrib; these indentures are alternate and blunt: the stalks rise a foot and half high, dividing upwards into several branches, having at each joint three narrow leaves sitting close to the stalks, from the base of which proceeds a leafy membrane or wing which runs along on both sides the stalk; these are rough and a little hairy: the stalks are terminated by panicles of flowers, which sit upon winged peduncles, each sustaining three or four flowers of a light blue colour, which continue long without fading: it flowers in July and August; but unless the summer is warm and dry, the seeds do not ripen in this climate. It is a native of Sicily and the Levant. There are two

varieties, which differ in their leaves, stems, and flowers.

Culture.—All the sorts are capable of being increased, by parting or slipping the roots: this, with the first kind, should be performed in the autumn or very early spring season, planting them immediately as edgings, or in the borders; they should not however be parted too small.

When planted out as edgings, a quantity of slips should be obtained in these seasons from old plants, by slipping or dividing the off-sets of their roots, each slip being furnished with roots and tops; then, having made up the edge of the bed or border even and firm, planting them either with a dibble in one range, two or three inches distance in the row; or to form at once a close edging, so near as to touch one another, or in a small trench, close, as in planting box edgings: these edgings should every summer, immediately after flowering, be trimmed with garden-shears, or a knife, to cut off all the decayed flower-stalks close to the bottom; likewise to trim in any projecting irregularity of the edging at the sides or top: also when it spreads considerably out of bounds, should be cut in evenly on each side, in due proportion; performing those trimmings in moist weather, and not too late in autumn, otherwise the drought of summer, or the cold in winter, will be apt to injure them when newly cut, and cause them to have a shabby disagreeable appearance: but when these edgings grow considerably out of bounds, or become very irregular, it is necessary to take them up, slip the plants small, and immediately replant them again as before, in a neat regular edging: they sometimes require replanting every three or four years in this manner.

The second sorts may likewise be raised by parting the roots in the autumn or spring, preserving some mould to them, and planting them out again immediately, being placed in an east border, where the soil is loamy.

They may also be raised from seeds obtained from abroad, sowing them on a similar border, keeping the plants clean, and when of sufficient growth planting them out in pots: it is the common practice in treating the second sort, according to Martyn, to consider it as a green-house plant; and it appears to the greatest advantage in a pot, as it is much disposed to throw up new flowering-stems: by having several pots, some plants will be in flower throughout the summer; on this account, and for the singularity of its large blue calyx, it is a plant that merits attention. The *Echioides* is also a green-house plant.

The eighth, ninth, tenth sorts, &c., may be increased by planting cuttings of the young

shoots, in July, in a shady border, watering them frequently: when the plants have a little growth, they should be taken up and placed in separate pots, filled with light loamy mould, putting them in the shade till rerooted: the plants of these sorts must be removed into shelter in the autumn, but they only require protection from hard frost, of course may be placed with myrtles, and other hardy green-house plants, where they often continue to flower a great part of winter, and make a pretty variety; these sorts afford variety among other potted more hardy green-house plants.

STAVE'S ACRE. See *DELPHINIUM*.

STOCKS, such young trees as are raised from seed, suckers, layers, and cuttings, and designed for the reception of grafts and buds of other trees, to continue them the same and become trees in every respect like the parent trees from which they were taken.

Stocks for general use are proper when from the size of a good large goose-quill to half an inch, or not more than an inch thick, in the part where the graft, &c., is to be inserted; but they are sometimes used when two or three inches in diameter: these are made use of in most kinds of fruit-trees, and occasionally for some varieties of forest and ornamental trees, and many of the shrub kind: they should in general be species or varieties of the same genus as the trees with which they are to be engrafted.

They are usually divided into three kinds; as *Crab Stocks*, *Free Stocks*, and *Dwarf Stocks*, each comprehending various sorts, both of the same and different genera, species, and varieties.

Crab Stocks.—These are all such as are raised from seeds, &c., of any natural or ungrafted trees, particularly of the fruit-tree kind; such as the crab-apple of the woods and hedges, any kind of wild thorny uncultivated pears, plums, wild black and red cherry, &c., and also of such trees as have been grafted or budded: some sorts, being strong shooters and hardy, are preferred, on which to graft particular species, to improve the size and duration of the trees; for example, apples are very commonly worked upon the common wild crab stock, and cherries on the great wild black and red cherry stock, as tending to promote a large, hardy, and durable growth, proper for common standards and the larger kinds of dwarf trees. In using crab stocks to graft any sorts of fruit-trees, it is proper to reject such of them as assume a very wild crab-like growth, or of a stumpy, thorny nature, preferring those that are the freest clean growers: sometimes, however, the appellation of crab stocks is given to all stocks indiscriminately,

before being grafted; whether raised from the seed, &c., of wild or cultivated trees, until worked with grafts or buds; but with the distinction of wild crabs, and free crabs.

Free Stocks.—This is commonly applied to such as are raised from the kernels of the fruit, layers, &c. of any of the cultivated garden and orchard fruit-trees and others, which often prove more free clean shooters than the wild crabs, and are more proper than they for choice apples, pears, peaches, nectarines, apricots, and plums, to improve the growth of the trees and quality of the fruit.

Dwarf Stocks.—These are such as are raised from low growing trees, of a shrub-like nature, or but very moderate tree-growth, being used for the lower and middling sorts of standards, and to form dwarfs, either for walls or espaliers, or as dwarf standards in small gardens, and others occasionally for variety, as well as for planting in forcing-frames, or to pot for forcing, or curiosity, &c., as the paradise apple and codlin stock, for dwarfing apples; the quince stock, for pears; the bird cherry, morello, and small May cherry stock, for cherries; the bullace and muscle stock for dwarfing apricots, peaches, and nectarines, and sometimes dwarf-almond stocks for the two latter, when designed to have these trees of a very dwarfish growth, either to pot for curiosity, or for forcing in small forcing-frames.

The most dwarfish kinds are: the paradise stock, bird-cherry, black bullace, and dwarf almond; but they are not so proper in general culture as common dwarf-trees, as they never attain a large growth, sufficient to produce any considerable quantity of fruit: the codlin dwarf stocks, quince stock, morello cherry, and muscle-plum stocks, are proper for the middling or larger kinds of dwarf trees, either for walls or espaliers, or dwarf and half standards: they are all raised from suckers, layers, or cuttings.

Sorts of Stocks adapted to each Kind.—For apples, in all the kinds, they are those of their own sort, raised from the kernels of any of the cultivated apples or crab for common standards, and the larger kinds of dwarfs; but the wild crab stock is often esteemed preferable to the free stock, for its hardy and durable nature, on which to graft common standards, and sometimes dwarfs for espaliers; and for lower dwarfs, the codlin, Siberian crab, and paradise stock are sometimes used; the former for middling dwarfs, and the latter for the smallest dwarfs: they are all easily raised, the free stock and crabs from the kernels of the fruit; and the codlin and paradise stock, likewise from suckers, layers, and cuttings. See *PYRUS MALUS*.

For the pear, it is chiefly grafted and budded on pear stocks for general use, but on quince for dwarfs; the former chiefly raised from the kernels of any sort of pears; and the latter freely by suckers, layers, and cuttings; but the pear stock is always to be preferred for the general supply of larger trees, for all common standards, and the larger dwarf pear trees for extensive walls and espaliers: the quince stock is estimable principally for its dwarfing property, or in being productive of moderate shooting trees for walls, espaliers, or middling standards, sooner arriving to a bearing growth. In order to form dwarf pears, white-thorn stocks, raised from seed, were formerly sometimes in repute, but they are very improper, as the trees rarely prosper well; as the goodness of the pear is often improved or diminished by the nature of the stock on which it is grafted, it is of importance to use free stocks, raised from the kernels of the best summer and autumn pears as much as possible; and the prime pears should be worked always on the finest free-shooting stocks of the most cultivated-like growths: sometimes, to improve the quality of particular choice kinds of pears, it is the practice to double work them, which is to graft the best sorts into free stocks in the spring, which shoot the same year; then about midsummer, or soon after, to bud the young shoots of the graft with buds of the prime sorts of pear, suffering only the shoots from the second budding to run up to form the tree: the breaking kind of pears are often rendered less hard and stony in this way, and the melting property of others is considerably improved. See *PYRUS communis*.

For quinces, two sorts of stocks are occasionally used, as that of its own kind, and the pear stock; the quince stocks are raised from seed, suckers, and cuttings, &c., and the pear kinds from the kernels of any sort of pears; but as all the varieties of quinces are so expeditiously raised with certainty the same by layers and cuttings, it renders the raising of stocks for grafting or budding them on almost unnecessary. See *PYRUS Cydonia*.

For plums, the operation is performed only upon stocks of their own kind, raised from the stones of any sort of cultivated plum, or by suckers and layers, as the most certain methods to obtain any particular variety of free plum stock, as the muscle-plum stock, which many prefer as the best stock of all on which to work the finer kinds of plums, as generally producing very thriving moderate-growing, fruitful trees; raising it, not from seed, which would vary exceedingly, but by suckers from the root of real muscle-plum trees, or of those worked upon

the true muscle stock, or from layer stocks of the muscle-plum tree: the plum will also grow upon the apricot and cherry stock, but not in a thriving state for any length of time. See *PRUNUS domestica*.

For cherries, the proper stocks are those of the cherry kind only; as the great wild cherry stock for large trees, the cultivated garden cherries for the more moderate growths, and the bird-cherry stock for small dwarfs: the two former are raised from the stones of the fruit, and the latter also by seed, or by layers and cuttings: for general use, the wild black and red cherry stocks, being strong free growers, are preferable for all common large standard cherries, also the larger dwarf-trees for extensive walls and espaliers; as these stocks, being of strong hardy growth, generally produce larger, more hardy and durable trees than the cultivated cherry stocks: sometimes stocks of the morello and May cherry, as being moderate growers, are used to raise the smaller cherry-trees, either in dwarfs for low walls and espaliers, or for small or moderate standards; but the former when raised from layers is more certain of producing the real sort in its naturally moderate growth: the common bird-cherry, as being a very moderate grower, is used to raise dwarf cherry-trees, either to plant in borders, pots, forcing-frames, or to pot for forcing, &c.: they are raised plentifully from seed, cuttings and layers; and have the effect of dwarfing trees exceedingly, so as to bear fruit when but one or two feet high; and shooting very little to wood, generally bear abundantly for their size: and cherries will also grow upon plum, apricot, and laurel stocks, as being of the same genus. See *PRUNUS Cerasus*.

For apricots, these prove the most durable on stocks of the plum kind, as common plum stocks of any variety for all common wall, espalier, and standard trees; and the bullace stock for small dwarfs; the plum stocks are raised from the stones of any kind of cultivated plum, or by suckers from the root; and the bullace from seed, suckers, and layers: though they succeed almost equally well upon stocks of any kind of plum, it is probable they may prove the most successful on the muscle-plum stock, like peaches, &c., as being of a more moderate regular growth, and more prolific nature: the bullace stock is only used occasionally to raise moderate small dwarfs for low walls, or to plant in pots, or in forcing frames for forcing: the apricot will likewise grow on its own, and on peach and almond stocks raised from the stones, but never in so prosperous or durable a manner. See *PRUNUS Armeniaca*.

For peaches, several sorts of stocks are occasionally used; as almond, peach, nectarine, apricot, and plum stocks: they are all raised from the stones of the fruit, and the latter also by suckers and layers; but the plum stock, being the most hardy, is the most proper for general use; but the free plum stock is preferable for all the sorts of peaches and nectarines, as being productive of the most hardy, thriving, and durable trees; though it is remarkable, one sort of plum stock in particular is generally preferable on which to work peaches, which is that of the muscle-plum, as producing the most prosperous trees, and of a more moderate, regular, and fruitful growth, the fruit being of a superior quality, when the stocks are genuine; being raised from suckers or layers of the true muscle-plum-tree, or by suckers from the roots of such peach, nectarine, plum, &c., as are worked on muscle-plum stocks, which generally send up plenty from the roots annually; planting them off at one year's growth into the nursery to train them for use: double stocks, or double working, is sometimes used for the more delicate peaches, to improve their bearing, and the flavour of the fruit.

For nectarines, the same stocks as in the peach are used: as almond, peach, nectarine, apricot, and plum; all raised as for the peach tree: the plum stock should be preferred in general as for peaches.

For almond-trees, when raised for their fruit, the approved varieties may be budded into stocks of any sort of almond, peach, nectarine, apricot, or plum, raised from the stones, and the latter also from suckers, &c., but the trees are generally the most hardy and durable on plum stocks. See *AMYGDALUS*.

For medlars, three or four different stocks are occasionally used, to raise the approved varieties: as the medlar, white-thorn, pear, and quince stocks, the three former raised from seed, and the latter from suckers, layers, and cuttings; the medlar seedling-raised stocks are very proper to graft the approved varieties; and the white thorn and quince stocks are only used occasionally; but free stocks, raised from the kernels, of medlars or summer or autumn pears, are preferable to the two last for all the varieties of common medlar, which, either on their own or pear stocks, generally assume a more free growth, and produce the fruit in greater perfection and abundance. See *MESEFILUS*.

For sweet service-trees, when designed as fruit-trees, the approved varieties should be grafted or budded upon proper stocks; either principally their own raised from the seed, or occasionally on pear or quince stocks, raised as for

the medlar and other trees; though any of the sorbus, or the pear, are preferable to the quince to work this tree on to have it large and durable: but quince stocks may be used to have trees of smaller growth, for low standards, espaliers, &c.

For the wild maple-leaved service berry-trees, the proper stocks are either their own kind, or those of the hawthorn, raised from the seed; they also take upon pear stocks, &c.

For hazel nuts, filbert, &c., the stocks of the common nut-tree, raised either from the nuts, or by suckers from the root, may be used; but this method is seldom employed. See *CORYLUS avellana*.

For orange trees, these are worked upon stocks of their own kind only, as any kind of orange, lemon, or citron stocks, raised from the kernels of the fruit; though the Seville orange, as being a very free strong shooter, is generally preferred for orange stocks; but the lemon and citron being also free growers form very proper stocks to raise any variety of oranges on. See *CITRUS Aurantium*.

For lemon and citron trees, these varieties are also budded or inarched upon lemon, citron, or orange stocks, raised from the kernels of the fruit, as for oranges. See *CITRUS medica*.

It is evident, that in this method, for curiosity, the same stock may be made to support two, three, or more different varieties of fruit, grafted or budded, either all into the stock, being previously trained with branches, forking off for the purpose one for each graft, or by cleft, or crown-grafting single large stocks, with two or more different sorts; or in smaller single stocks, by inserting two or more different buds by inoculation; likewise, the stock being singly grafted or budded, different sorts may be inserted into the shoots arising from the graft or buds; and thus two, three, or more sorts of apples may be had on the same root; and by the same method, different sorts of fruit may be had upon the same stock, as plums, cherries, and apricots all on a plum stock; or peaches, nectarines, and apricots on the same, or on stocks of their own kind; and pears, medlars, and quinces upon the pear stock; also red and white currants, or currants and gooseberries, on a currant or gooseberry stock; or white and red grapes on a vine stock; likewise red and white roses, or other different sorts, upon a common rose stock; as well as on numerous other trees and shrubs, which are species or varieties of the same genus.

Raising the Stocks.—All the different sorts may be raised by seeds, suckers, layers, and cuttings.

In the first mode, various sorts of stocks may

be raised from the stones and fruits of different sorts of trees: as the kernels of all the apple kinds, pears and quinces; and the stones of plums, cherries, apricots, peaches, and nectarines; the seeds or stones of medlars, services, &c.; also nuts, when designed for stocks; all of which should be obtained in autumn from their respective fruits when fully ripened; and when well cleared from the pulpy substance, each sort may be sown separately, in beds of common light earth in the nursery, either directly, or after being preserved in sand till February, but the early autumn is the best season; and if the winter should prove severe, the beds of the more tender kinds, as almonds, and peaches, &c., may be covered with dry litter to defend the seed from the frost. See *NURSERY*.

Before the appearance of the plants above ground, where the surface of the bed is hard bound or caked, it is beneficial to stir the surface lightly with a small iron rake; also, if very dry weather prevails, to give frequent moderate waterings, both before and after the plants are up, repeating the waterings occasionally in dry weather all spring and early part of summer, to encourage a free strong growth; being likewise careful to keep the beds very clean from weeds by diligent hand-weedings; and by thus giving every encouragement, the seedling stocks will grow so freely during the summer, as by autumn or spring following to be mostly of a proper size to plant out into nursery lines in the open quarters, in rows two feet asunder, to remain for grafting and budding; though, if they have made but middling progress the first summer in the seed-bed, and are rather small and weakly, the strongest only should be planted out, leaving the rest growing until next autumn, when they will be all of full size for planting out wholly into the open prepared nursery quarters, forking the seedling plants up out of the beds, shortening any perpendicular tap-root and long stragglers, but leaving all their tops entire, and then planting them in lines, either by trench-planting, slit-planting, or dibble-planting, as the sizes of the plants admit, in rows two feet or two feet and a half asunder, setting the plants one foot or fifteen inches apart in each row, in an upright position; and after having planted one row, treading the earth gently all along close to the roots of the plants, to fix them firmly in the earth all evenly in a straight range, proceeding in the same manner, row and row, till the whole is planted, levelling the surface of the ground between all the rows with the spade or rake: their future culture, till grafted or budded, consists in occasional waterings in the first spring, hoeing over the ground every summer, digging

between the rows annually in the winter or spring; and training the stocks each to one stem; preserving their top always entire; but trimming off the strong laterals below, to encourage the strength of the main stem, when they will be fit for grafting or budding, in from one to two or three years. See PLANTING.

They are proper for working when from about the size of a large goose-quill, as already observed, to the thickness of a man's little finger, or a little more; but the sooner they are worked after they are of a due size, the better they succeed, and the sooner they form trees. See GRAFTING and BUDDING.

In some cases, however, where the stocks have shot freely the first summer after planting out from the seed-bed, many of them may probably be of a due size to graft the following spring and summer, at five or six inches height, to form dwarfs for walls and espaliers, &c., or even, in some sorts, for full or half standards, provided the first main shoot from the graft or bud is trained up singly, two or three years, to form the stem, of from four or five to six or seven feet stature: however, if they have grown but moderately the first and second seasons, and are not generally in a condition for the operation of grafting or budding, it is better to let them have another year's growth.

In the second mode, the suckers of all the trees which afford them should be planted off at one year's growth in autumn, winter, or spring, which is a very expeditious method of raising several sorts of stocks; so that, after being transplanted into the nursery, they often in one or two years' growth afford proper stocks for the reception of grafts and buds; and many of them are often fit for budding in the summer following, at the proper budding season, or for grafting the spring after.

The suckers are generally fit to take up for the purpose of stocks, when of one year's growth, about the size of a tobacco-pipe, or but little bigger, and should be collected in autumn or the early part of winter; taking them up as well rooted as possible, cutting off all knots or knobbed woody parts of the old roots that may adhere to their bottom, trimming the straggling fibres, and cutting off all side-shoots from the stem; then planting them in rows two feet asunder, and one foot distant in the lines; treading the mould gently to their roots, and finishing the work by levelling the surface between the rows: the culture afterwards, till grafted or budded, is nearly the same as that of the seedling stocks, keeping them clean from weeds in summer by hoeing; and probably some of the strongest shooters may be fit to bud in the July

VOL. II.

or August following; though the general part will require two years' growth before they are proper for working; still continuing them all to one stem, by timely displacing strong laterals, and preserving their top or leading shoot generally entire until grafted, &c.

The third method is practised for some sorts of stocks of fruit and other trees, and when any particular variety of stock is required, such as the paradise stock for apples, muske-plum for peaches, &c., that they may be obtained of the real sort with certainty: but as this method of raising stocks would be attended with great trouble for general grafting and budding, it is only practised occasionally. In providing them in autumn or winter, some of the young shoots of such trees as have the branches naturally growing near the ground, or in which the stems have been cut down low while young, to force out branches near the bottom, to furnish shoots properly situated for laying, should be slit-layed in the common method, when they will mostly be rooted by the autumn following, and be fit to take off and plant into the nursery, being managed as directed for the seedling and sucker stocks.

In the last method, cuttings of the last year's shoots should be chosen in autumn, planting them in the nursery, in a somewhat shady border, giving occasional waterings the following spring and beginning of summer in dry weather, when they will be mostly well rooted by next autumn, and may be then planted out in nursery-rows two feet asunder, managing them as the others: they should be kept with upright stems, except any should assume a stunted or crooked growth, in which case they should be headed down to the ground in spring, when they will push out strong from the bottom the ensuing summer, training them to one stem, and with their leading top-shoot entire as above; and according as all the sorts advance in growth, they should be divested of strong lateral shoots below, repeating it particularly in the taller standard stocks, to encourage their upright direction more expeditiously to the proper grafting and budding heights.

The proper methods of grafting, and budding are shown under the culture of the different kinds.

STONE-CROP. See SEDUM.

STONE-CROP TREE. See CHENOPodium.

STOOLS, such headed-down young trees and shrubs in the nursery as are appropriated for the production of an annual supply of lower shoots or branches near the ground, properly situated for layering. See LAYING.

Trees and shrubs for this purpose are generally headed down to the bottom in the nursery,

&c., in order to force out more effectually a plentiful supply of branches near the ground, to afford layers conveniently situated for laying down in the earth, which being layed in autumn, winter, or spring, they strike root in a year or two; each layer commencing a distinct plant, and is planted off into the nursery in autumn following; the stools, remaining, send out a further supply of lower shoots the following summer, for laying as before; and thus the same stools continue affording supplies fit for laying annually, or every other year: for this purpose, some of the strong young trees and shrubs should be chosen, which should be planted in the nursery, &c., at from five or six, to eight or ten feet distance, according to their size or nature of growth; and after having remained a year or two till firmly rooted, and they have acquired some substance, all those of the tree kind, or such others as run up with stems, without affording lower branches near the ground for laying, should, in the autumn, winter, or early in the spring, be headed down within a few inches of the ground; by which, in the summer following, they push out from the bottom plenty of strong young shoots near the ground for laying, which may be put down in the succeeding autumn, winter, or spring; or, if any remain, till the second autumn, the first shoots sending out many lateral or side shoots the ensuing summer, which may furnish an additional supply, of a proper growth for laying; these small laterals being often better adapted for rooting than the first vigorous shoots that rise immediately from the stool, and each of which layed will form a new plant. See LAYING.

Every year, soon after the layers are separated from the stools, the latter should be dressed, by cutting off all the parts of old branches and scraggy stumps from the head, within an inch or two of the main stool; and then digging and levelling the ground neatly about and between the whole, and in the spring and summer giving occasional hoeings in dry weather to destroy weeds: sometimes stools for layers are formed occasionally of trees, &c., that are considerably grown up, not having been headed down to form low stools, but the branches of which are of considerable height from the ground; in which case, the branches, if flexible and long enough, are bowed down to the earth; or, if inflexible and too stubborn to bend, are plashed, by making a gash or cut on the upper side; or if too large for plashing, or the nature of the wood does not bear that operation, the tree or shrub is sometimes thrown on its side by opening the earth about the roots, loosening or cutting those on one side to admit of lowering the

head sufficiently for laying the branches in the ground; and sometimes, when stools are formed from grown-up trees, whose branches are too high for laying in the full ground, a temporary stage or scaffold is erected, on which the pots or tubs of earth are placed for the reception of the layers. See LAYING.

STOVE, a sort of garden-building or erection constructed with brick-work behind and on the north, as well as partly in front, and roofed wholly with glass sashes to the south, being furnished internally with a pit, or long, wide, deep cavity, for a bark hot-bed or beds, and with flues round the inside of the walls for fire-heat; the whole calculated to produce a certain temperature at all seasons, adapted to the culture of the tenderest exotic plants, as well as for forcing various kinds, both hardy and tender, into flower and fruit, &c., at an early season; and which was so named before the use of bark-beds, from being worked only by means of fire-heat. See HOT-HOUSE.

Besides their use in the growth and preservation of various tender exotic plants as just noticed, by their means the gardener is also enabled to forward many hardy plants to early perfection; such as various sorts of curious flowers, fruits, salad-herbs, kidney beans, strawberries, &c., probably one, two, or three months sooner than they could possibly be obtained in the open ground; and likewise many sorts of seeds, cuttings, and layers of exotics are made to grow freely in the bark-bed of the stove, that without such aid would not grow at all in this country; also cuttings, &c., of many curious hardy plants that root reluctantly in the full ground, are facilitated considerably in their rooting by the bark-bed of this department.

Different sorts of stoves are used occasionally for different purposes; as the *Bark Stove*, for common use, which has both a bark-bed and flues: the *Dry Stove*, for particular succulent plants, &c., which is furnished only with flues for fire-heat, having no bark-bed: the *Forcing Stove*, which is employed purposely for forcing hardy fruits, flowers, &c., into early perfection; being constructed both with bark-bed and flues, or only with flues.

By the uniform moderate moist growing heat in the first sort of stove, many kinds of such plants as have been mentioned are brought forward and preserved, and in which, some require the bark-bed, others succeed in any part of the house; and still others, as the succulents, require the driest situation near the flues: many of the more tender, herbaceous, and shrubby plants succeed best when plunged in the bark-bed, though the greater part of the herbaceous and

whody sorts succeed well enough in any part: the bark-bed is principally allotted for the pine-apples; and most of the smaller succulents, particularly, may be stationed mostly over the top of the flues upon shelves out of the way of moisture, as being naturally very replete with humidity: and the hardy plants designed for forcing, such as strawberries, kidney beans, and various sorts of flowers, &c., that are potted, may be placed upon shelves, or on the parapet wall of the bark-bed; but the nearer the glasses the better, particularly the strawberries; but good early kidney beans may be raised in almost any part of the stove. When any sort of flowers are to be forwarded, such as roses, pinks, &c., or any bulbous flowers, as early as possible, they may be plunged in the bark-bed, and some be placed upon shelves, &c., to succeed them. See HOT-HOUSE.

The second sort of stove, from its affording a dry heat, is intended principally for the culture of very succulent tender exotics of parched soils, that require to be kept always dry. Where there are large collections of this sort of plants, it is very useful to deposit the most succulent of them in separate stoves, for fear of the others which perspire more freely occasioning a damp air in winter, which may be imbibed by the succulents, and injure them, as being impatient of much moisture, particularly in that season: in this kind of stove moveable stands or shelves are erected above one another, on which to place the pots of plants; such as the tenderer sorts of aloes, cereuses, euphorbiurns, melon-thistle, and other very tender succulent plants, &c.; but most of them may be cultivated in a common stove.

The third sort of stove is sometimes used principally for flowers, as is common about London, to force large quantities of early roses, pinks, and numerous other flowers for market, where they fetch a very great price at an early season: others are intended principally for fruit-trees, and some serve both for forcing flowers and fruits, and several sorts of small plants, as strawberries, kidney beans, &c.; so that they consist of two kinds, which are a bark forcing stove, furnished with a bark-bed and flues; and a fire forcing stove having only flues for fire without any bark-bed: the former of which is constructed like a common bark stove, being furnished with a pit for a bark-bed to receive the pots of particular sorts of plants intended for forcing, in order to forward them as early as possible; and with flues for fire-heat occasionally; and sometimes it is formed capacious enough in width to admit of a border of earth behind the bark-bed, next the back wall, serving for

fruit-trees, to be planted in the full ground; such as cherries, peaches, apricots, &c., for early forcing: the bark-bed is for receiving various sorts of plants in pots in winter, for forcing to maturity of growth or production in that season or early in spring; as pots of roses, pinks, dwarf tulips, hyacinths, narcissuses, honeysuckles, hypericums, and many other flower plants of small or moderate growth, both of the shrubby and herbaceous kinds; also any curious tender annual flowers, such as balsamines, &c., may be forwarded in it; likewise pots of strawberries, dwarf cherries, and other small fruits plunged either in the bark-bed, or placed any where towards the glasses; also pots or boxes of kidney-beans, salading, &c.

The season to begin forcing in these stoves is principally from about the latter end of December to the end of January, according as the flowers, fruits, &c., may be wanted; the plants and trees intended for forcing in pots should have been potted either a year before, or in the preceding spring or autumn, and in winter sheltered from severe frost till the forcing time: it is necessary for the shrub and tree kinds in particular, as if planted or potted the preceding year or before, and they are well rooted and firmly established in the earth, it is of essential advantage; being all previously raised in the open ground, till advanced to a proper growth for flowering and fruiting; and the fruit-trees at the same time, trained in the requisite order: those intended for planting in the internal border of earth behind should be planted fully therein early in autumn, without being potted; some of which, such as peaches, nectarines, apricots, &c., being trained as wall-trees, others as low standards, particularly cherries; and vines, planted also against the front without-side, have the stems trained in through small holes, and conducted up under the sloping-glasses; but such plants as are to be raised from seed should not generally be sown till the time the pots are placed in the stove for forcing.

When the plants, seeds, &c., have been properly arranged in these stoves, they are soon set in motion by the bark-bed heat, and afterwards by making moderate fires on cold nights, and on days occasionally, in very severe weather, to support a constant proper warmth to continue the plants always in moderate growth; by which means, various flowers and fruits may be obtained two or three months before their natural season in the open air.

The latter kind, or such stoves as are worked by fire-heat only, are mostly used for forcing fruit-trees, having the whole or most part of the bottom space within formed of good rich earth,

full two feet deep, in order to plant the fruit-trees entirely in the ground to remain; an alley or walk being either formed next the back wall, or carried along the middle, allotting a raised border along the back part, for the reception of the choicer fruits to be trained as wall-trees; and the main middle space for small standards of moderate growth: in these the best sorts of apricots, peaches, nectarines, cherries, plums, vines, and figs; likewise any small fruit plants, as gooseberries, currants, raspberries; also tufts of strawberries, which should all be first trained in the open ground to a bearing state; may be introduced: the peaches, nectarines, apricots, and figs, should be planted principally toward the back wall, and trained to a treillis as wall-trees: the cherries as standards, both small-headed, moderate, full standards, half standards, and dwarfs, disposed in the middle space, the tallest behind, and the lowest forward; with pots of strawberries and low flowers, upon shelves near the glasses; and the vines either within towards the front, or wholly without, close against the front wall, and the stems, or a strong shoot of each plant drawn in through a small hole made for each, either in the wall, or in the timber of the front erections; and the branches within trained up to the inside of the sloping glass upon treillis work: in the vines planted on the outside, it is necessary to guard the stems in winter, especially some time previous to, and during, the forcing season, with hay-bands wrapped closely round them, also to lay some dry mulch over the roots, to protect the whole as well as possible, that the progress of the sap may not be much retarded by the external cold, and to promote its flowing more freely for the advantage of the internal growth of the vines, &c.

The season to begin forcing or making the fires in these stoves is January, or early in February, continuing it moderately every night and morning, during the cold weather in winter and spring, to forward the different fruits to as early perfection as possible. See HOT-HOUSE.

STORAX. See STYRAX.

STOVE PLANTS, such tender exotics from the hot parts of the world as require the aid of the stove to preserve them in this climate.

The following are the principal sorts cultivated in this country in these departments:

TREE KINDS.

Abroma, Maple-leaved *Abroma*.
Achras Sapota, Mammee-tree—Common *Sapota*—Mammee *Sapota*.
Adansonia, Ethiopian Sour Gourd.
Adenanthera, Bastard Flower Fence—*Pavonia*—*Falcotaria*.
Anacardium, Acajow-, or Cashew-Nut.

Annona, Custard Apple—Nettled Custard Apple—Prickly Custard Apple—Scaly Custard Apple, or Sweet Sop—Marsh *Annona*, or Water Apple—Broad-leaved *Annona*.

Bombax, Silk Cotton-Tree—Thorny *Bombax*, or Cuba—Pentandrous Smooth *Bombax*—Hep-taphyllous Smooth *Bombax*.

Carica, Papaw or Pepo Tree—Common Indian Papaw Tree—Posoposa, or Branching Surinam Papaw Tree.

Cassia, Wild Sena—Purging-Tree *Cassia*—Billorous Shrub *Cassia*.

Cedrela, Bastard Cedar.

Chamaerops, Dwarf Palm, or Palmetto. (Fron-dose.)

Chiococca, Snowberry-Tree.

Chrysobalanus, Cocoa Palm.

Cinchona, Jesuit's Bark-Tree.

Clusia, Balsam-Tree.

Cocos, Cocoa-nut Tree. (Fron-dose.)

Crataeva, Garlic Pear.

Crescentia, Calabash Tree.

Croton, Tallow Tree.

Dracena, Dragon Tree.

Fagara, two species.

Ficus, Fig Tree—Sacred Fig, or Indian God-Tree—Sycamore Fig Tree—Bengal Fig Tree—Indian Long-leaved Fig Tree—Dwarf Indian Fig Tree.

Guaiacum, Lignum Vitæ; three species.

Guetarda, one species.

Guilandina, several species.

Hæmatoxylum, Blood-wood, or Log-wood..

Helicteres, Screw Tree.

Hernandia, Jack-in-a-Box Tree—Sonorous *Hernandia*—Oriental *Hernandia*.

Hymenæa, American Locust Tree.

Laurus, Bay Cinnamon Tree—Alligator Pear.

Mammea, Mammee Tree—American Mammee Tree—Asiatic Mammee Tree.

Mangifera, Mango Tree.

Melastoma, American Gooseberry.

Melia, Bead Tree—Evergreen Bead Tree of Ceylon—*Azadirachta*, or Indian Bead Tree.

Musa, Plantain Tree; all the three species.

Myrtus, Myrtle Tree—Pimento, or All-spice Tree—Diocious Myrtle—Brazilian Myrtle, &c.

Parkinsonia, Parkinsonia.

Physalis, Winter Cherry.

Robinia, False Acacia—Violet American *Robinia*—Smooth Indian *Robinia*.

Sapindus, Soap-berry Tree.

Swietenia, Mahogany Tree.

Tamarindus, Tamarind Tree.

Theobroma, Chocolate-nut Tree—Cocoa, or Chocolate-nut Tree—*Gauzuma*, or Bastard Cedar of Jamaica.

Tinus, several species.

Toluifera, Balsam of Tolu Tree.
Ximenia, American Prickly Ximenia—Unarmed Jamaica Ximenia.
Zamia, Dwarf American Palm. (Fronlose.)

SHRUBBY KINDS.

Abrus, Jamaica Wild Liquorice.
Amyris, Sweet Wood.
Apocynum, Dog's Bane—Shrubby Upright Ceylon Apocynum, with varieties—Climbing Dog's Bane, with varieties.
Banisteria, several species.
Bauhinia, Mountain Ebony—Prickly Bauhinia—Tomentose Bauhinia.
Begonia, Shining-leaved.
Bellonia, Rough-leaved.
Bixa, Dyeing Metella, &c.
Bocconia, Tree Celandine.
Bontia, Barbadoes Wild Olive.
Brunia, several species, either for the stove or greenhouse.
Brunsfelsia, Brunsfelsia.
Buddleia, American Buddleia—Occidental Buddleia.
Camellia, Japan Rose.
Capparis, Caper Bush.
Capsicum, Guinea Pepper—Shrubby Capsicum, with many varieties.
Catesbea, Lily Thorn.
Ceanothus, New Jersey Tea—Asiatic Ceanothus.
Celastrus, Staff Tree; two or three species for stove or green-house.
Cestrum, Bastard Jasmine, or Jasminoide.
Citharexylon, Fiddle Wood.
Cliffortia, three species, for stove or green-house.
Clitoria, three species.
Cluytia, Elutaria, or Indian Cluytia.
Coccoloba, Sea-side Grape.
Coffea, Coffee Tree.
Crotalaria, Laburnum-leaved.
Dracontium, Dragons.
Ehretia, two or three species.
Elæocarpus, one species.
Eriocephalus, three species, for the stove or green-house.
Erythrina, Coral Tree—Corallodendron, or Smooth Coral Tree—Spinous Coral Tree.
Gossypium, Cotton-plant; consists of herbaceous and shrubby species. See GOSSYPIMUM.
Grewia, Oriental Grewia.
Heliotropium, Turnsole.
Hibiscus, Syrian Mallow—Mutable-flowered Hibiscus, or China Rose—*Rosa Sinensis*, or Rose of China—Viscous Mallow, or Scarlet Hibiscus.
Indigofera, Indigo.
Ixora, Indian Wild Jasmine.

Lantana, American Viburnum—Trifoliate Lantana—Involucrum-headed Lantana—Camara, or Leafless-headed Lantana—Prickly Lantana.

Lawsonia, Lawsonia.
Lobelia, Cardinal-flower—Plumier's Lobelia—Surinam Lobelia—Pine-leaved Lobelia.
Loranthus, Loranthus.
Mesua, Indian Rose Chesnut.
Mimosa, Sensitive Plant. All the species.
Nerium, Oleander—Double-flowered—Striped-leaved.
Nyctanthes, Arabian Jasmine—Sambac, or Common Arabian Jasmine—Undulate-leaved Nyctanthes, or Malabar Jasmine—Arbor Tristis, or Sorrowful Tree—Hairy Sorrowful Tree.
Ophioxylon, Climbing Ophioxylon.
Panax, Genseng.
Pentapetes, Shrubby Pentapetes.
Phyllanthus, Sea-side Laurel.
Phytolacca, American Nightshade.
Piscidia, two species.
Poinciana, Barbadoes Flower Fence, &c.—Fair Poinciana, or Double-spined Barbadoes Flower Fence—Bijugated Single-spined Poinciana—Spineless Poinciana.
Portulaca, Purslane.
Ptelea, Shrubby Trefoil, Viscous Indian Ptelea.
Randia, two species.
Rauwolfia, Rauwolfia.
Rhamnus, Buckthorn—Spina Christi, or Ethiopian Jujube—Cenoplia, or Ceylon Jujube.
Rhus, Sumach—Cobbe, or Ceylon Sumach.
Sideroxylon, Iron Wood—Inermis, or Smooth Ethiopian Sideroxylon—Spinous Malabar Sideroxylon.
Solanum, Nightshade—Guinea Nightshade—Fiery-thorned Nightshade—Bahama Nightshade—Trilobate Nightshade, &c.
Sophora, Sophora.
Spothelia, Spothelia.
Tabernæmontana, Tabernæmontana.
Tournefortia, Shrubby Tournefortia—Vulbilate or Twining Tournefortia—Fætid or Stinking Tournefortia—Hairy Tournefortia—Serrated Tournefortia—Cymose Tournefortia.
Vinca, Periwinkle—Rose Periwinkle of Madagascar.
Vitis, Vine—Indian Wild Vine—Trifoliate Indian Vine.

UNDER-SHRUBBY KINDS.

Acanthus, Bear's Breech—Shrubby Holly-leaved Acanthus.
Volkameria, Prickly Volkameria—Unarmed or Smooth Volkameria.

HERBACEOUS KINDS.

Achyranthes, Bloody or Red Indian Achyranthes—Woolly-cupped Indian Achyranthes.

leaved Euphorbia—Medusa's Head Euphorbia—
Tithymeloid Euphorbia, or Bastard Spurge.

Glaxinia, one species.

Stapelia, Variegated Stapelia—Hairy Stapelia.

BULBOUS KINDS.

Antholyza, Æthiopian Corn Flag; several species.

Crimum, Asphodel Lily—American Asphodel Lily—Asiatic Asphodel Lily.

Limodorum, Limodorum.

Massonia, Broad-leaved—Narrow-leaved.

Pancratium, (Pancratium Lily) Sea Daffodil—
Ceylon Uniflorous Pancratium—Mexican Biflorous Pancratium—Caribbean Multiflorous Pancratium—Amboyna Broad-leaved Pancratium.

Some of these sorts of plants are also inserted in the green-house list; as, where there is no stove, they may be preserved tolerably well in a good greenhouse.

STRAWBERRY. See FRAGARIA.

STRAWBERRY BLITE. See BLITUM.

STRAWBERRY SPINACH. See BLITUM.

STRAWBERRY TREE. See ARBUTUS.

STRELITZIA, a genus affording a plant of the herbaceous exotic perennial kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Scitamineae*.

The characters are: that the calyx is an universal spathe, terminating, one-leaved, channelled, acuminate, from spreading declining, many-flowered, involving the base of the flowers; partial spathes lanceolate, shorter than the flowers: perianth none: the corolla is irregular: petals three, lanceolate, acute; the lowest boat-shaped; the two upper bluntly keeled: nectary three-leaved: the two lower leaflets a little shorter than the petals, from a broad base awl-shaped, waved at the edge, folded together, including the genitalia, towards the tip behind augmented with a thick appendix, in form of half an arrow head; the lowest leaflet short, ovate, compressed, keeled: the stamina have five filaments, filiform, placed on the receptacle: three is one leaflet of the nectary; two with the style inclosed in the other leaflet: anthers linear, erect, commonly longer than the filaments, included: the pistillum is an inferior germ, oblong, obtusely three-cornered: style filiform, length of the stamens: stigmas three, awl-shaped, higher than the petals, erect, at the beginning of flowering time glued together: the pericarpium is a subcoriaceous capsule, oblong, obtuse, indistinctly three-cornered, three-celled, three-valved: the seeds numerous, adhering in a double row to the central receptacle.

The species is *S. Reginae*, Canna-leaved Strelitzia.

It has all the leaves radical, petioled, oblong, quite entire, with the margin at bottom waved and curled, very smooth, glaucous beneath, coriaceous, a foot long, permanent: the petioles somewhat compressed, three feet long and more, the thickness of the thumb, sheathing, erect, smooth: the scape the length and thickness of the petioles, erect, round, covered with alternate, remote, acuminate sheaths, green with a purple margin: the general spathe a span long, green on the outside, purple at the edge; partial spathes whitish: the petals yellow, four inches long: the nectary blue: according to Curtis, the spathe contains about six or eight flowers, which becoming vertical as they spring forth, form a kind of crest, which the glowing orange of the corolla, and fine azure of the nectary, render truly superb. A native of the Cape.

Culture.—These plants are raised from seeds, brought from their native situation, and sown in pots of good fine mould, plunged in a hot-bed to get them up; the plants when of some growth should be removed into separate pots, and be replunged in the tan-pit of the stove; afterwards, when the plants are large, they should have plenty of mould, that the roots may be extended into the rotten tan, and in that way render them more strong for blowing their flowers: it may likewise sometimes be raised from the roots, when they are suffered to strike in the above manner; it is said to succeed best in the dry stove and conservatory.

It is highly ornamental among stove plants.

STUARTIA, a genus furnishing a plant of the hardy deciduous flowering shrubby kind.

It belongs to the class and order *Monadelphia Polyandria*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a one-leaved perianth, half-five-cleft, spreading; segments ovate, concave, permanent: the corolla has five petals, obovate, spreading, equal, large: the stamina have numerous filaments, filiform, united into a cylinder below, shorter than the corolla, connecting the petals at the base: anthers roundish, incumbent: the pistillum is a roundish germ, hirsute: style simple, filiform, length of the stamens: stigma five-cleft: the pericarpium is a juiceless pome, five-lobed, five-celled, soluble into five closed parts: the seeds solitary, ovate, compressed.

The species cultivated is *S. Malacodendron*, the Malacodendron.

It is a shrub, rising with strong ligneous stalks to the height of ten or twelve feet, sending out branches on every side covered with a brown bark, and garnished with oval spear-shaped leaves, about two inches and a half broad, sawed

on the edges, pretty much veined, and stand alternately: the flowers are produced from the wings of the stalk; they are white, with one of the segments of a yellowish tinge: it flowers in the latter end of May. It grows naturally in Virginia.

Culture.—This plant may be increased by seeds, layers, and occasionally by cuttings: the seeds should be procured from abroad, and sown in pots, filled with light earth, in the early spring, plunging them in a good hot-bed, watering them well now; and when the plants are up protecting them under frames, or in the green-house, for two or three winters, and hardening them in the summer, then putting them into small pots separately, in the spring placing them in the hot-bed till fresh rooted, watering them occasionally, and giving proper shade till fresh rooted, then hardening them for the summer, but protecting them in the following winter: then in the spring following, when the weather is fine and settled, turning them out with balls about their roots into the open ground, placing them in a warm situation. The young shoots may be laid down early in the autumn, in the slit method, watering them frequently in the following spring and summer, and shading them from excessive heat: when well rooted, in the following spring they may be taken off and planted out in separate pots, plunging them in a hot-bed till they have taken fresh roots, when they should be managed as the others.

The cuttings of the young shoots should be planted out in the spring, in pots of fine light mould, plunging them in a hot-bed; and when they have stricken good roots they may be removed into separate pots and managed as the others.

These plants afford ornament and variety in shrubberies, and among potted plants.

STYRAX, a genus furnishing an aromatic deciduous tree of the exotic kind.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Bicornes*.

The characters are: that the calyx is a one-leaved perianth, cylindric, erect, short, five-toothed: the corolla one-petalled, funnel-form: tube short, cylindric, length of the calyx: border five-parted, large, spreading; segments lanceolate, obtuse: the stamina have ten filaments, erect, in a ring, scarcely united at the base, awl-shaped, inserted into the corolla: anthers oblong, straight: the pistillum is a superior germ, three-celled, many-seeded: style simple, length of the stamens: stigma truncate: the pericarpium is a roundish drupe, one-celled: the seeds are nuts one or two, roundish, acuminate, convex on one side, flat on the other.

The species is *S. officinale*, Official Storax.

It rises in its native situation twelve or fourteen feet high: the trunk is covered with a smooth grayish bark, and sends out many slender branches on every side; the leaves about two inches long, and an inch and half broad, of a bright green on their upper side, but hoary on their under; they are entire, and placed alternately on short footstalks: the flowers come out from the side of the branches, upon peduncles sustaining five or six flowers in a bunch; are white, and appear in June. It is a native of Italy and the Levant.

Culture.—It may be increased by seeds, obtained from abroad, by sowing them in pots of light earth an inch deep; and as they are of a hard stony nature, and rarely come up the first year, the pots should be plunged under a frame during cold weather, and be in the shade in summer, and in the second spring be plunged in a hot-bed to forward them, being careful to give water, and to harden the young plants gradually to the full air in summer, in a shady place during the hot weather, being often watered; and in winter the pots be replaced under a garden-frame, &c., to have shelter from frost; then in spring following let them be potted off separately, and managed as hardy green-house plants for three or four years, when some of them may be turned out into the full ground in a sheltered situation, trained against a south wall, and some may be retained in pots for the green-house collection: they afford ornament and variety in these different situations.

STYRAX. See LIQUIDAMBAR.

SUBER. See QUERCUS.

SUCKERS, such young offspring plants as arise immediately from the roots of older vegetables, and which, being generally furnished also with roots, when transplanted, readily grow, and become proper plants, similar to the mother ones.

They are proper for increasing their kinds by in many cases, and in certain instances a sure method to continue any approved or desirable species or variety; but in grafted and budded trees, the suckers partake only of the nature of the stock.

Some sorts of trees furnish plenty every summer, which are often furnished with root-fibres, affording proper plants for setting out in one season, and of course become a ready means of increase: in trees, &c., that are wholly the same sort, root and top, they prove the same invariably in every mode of growth, as certainly as by layers, cuttings, grafting, &c.

The season for taking up or transplanting suckers of trees and shrubs, is almost any time, in open weather, from October till March, being careful to dig them up from the mother plant with as much root-fibres as possible, and trim-

ring them ready for planting, by shortening the long straggling fibres, and cutting off any thick-knobbed part of the old root that may adhere to the bottom, leaving only the fibres arising from the young wood; though it is probable some will appear with hardly any fibres; but as the bottom part having been under ground, and contiguous to the root of the main plant, is naturally disposed to send forth fibres for rooting, preparatory to planting them out, the stems of the shrub and tree suckers should likewise be trimmed occasionally, by cutting off all lower laterals; and any having long, slender, and weak tops, or such as are intended to assume a more dwarfish or bushy growth, may be shortened at top in proportion, to from about half a foot to one or two feet in length, according to their nature or strength; and others that are more strong, or that are designed to run up with taller stems, may have their tops left entire, or shortened but little: when thus taken up and trimmed, they should be planted out in rows in the nursery; the weak suckers separately in close rows; and also the shortened and stronger plants each separately in wider rows; so that the rows may be from one to two feet asunder, in proportion to the size and strength of the suckers: and after being thus planted out, they should have the common nursery culture of cleaning from weeds in summer, and digging the ground between the rows in winter, &c., and in from one to two or three years they will be a proper size for planting out where they are to remain: and some kinds of trees, &c., produce suckers strong enough in one season to be fit for planting where they are to remain: as some sorts of roses, and numerous other flowering shrubs; also some of the strong shooting gooseberries, currants, raspberries, &c.

The increase by suckers, as in some particular sorts of trees and shrubs, as currants and gooseberries, &c., is objected to for any general supply, on the supposition that the trees so raised are more adapted to run too greatly to suckers, and overrun the ground round the mother plant, than such as are raised by other methods: however, it may generally be observed of such trees and shrubs as are naturally disposed to send up many suckers, that by whatsoever method they are propagated, whether by seeds, suckers, layers, cuttings, &c., they commonly still continue their natural tendency.

When it is therefore required to have any sorts produce as few suckers as possible, not to overrun the ground, or disfigure the plants, it is proper both at the time of separating the suckers, or planting them off from the main plants, and at the time of their final removal from the nursery, to observe if at the bottom part they

Vol. II.

show any tendency to emit suckers, by the appearance of prominent buds, which, if the case, should all be rubbed off as close as possible: as, however, many sorts of trees and shrubs are liable to throw out considerably more than may be wanted, they should always be cleared away annually at least, and in such as are not wanted for increase, it is proper to eradicate them constantly, as they are produced in spring and summer.

Numerous herbaceous and succulent plants are productive of bottom off-set suckers from the roots, by which they may be increased, either generally or occasionally, according to the different sorts, both of the fibrous-, bulbous-, and tuberous-rooted tribes; all the off-sets from the root, and above-ground bottom side heads, of these kind of plants, may be deemed a sort of suckers: those for planting should be taken off when of one summer's growth, or two at most, which, in the fibrous-rooted kind, may be performed in autumn or spring; and in the bulbous-, and many of the tuberous-rooted sorts, in summer and autumn, when the stalks and leaves decay.

In slipping and planting these sorts of off-set suckers, the smaller ones should be planted in nursery-beds, pots, &c., according to the nature of growth and temperature of the different sorts, to have the advantage of one summer's advanced growth; and the larger ones at once, where they are to remain, in beds, borders, pots, &c., according to the sorts.

SUN, the luminary that affords light and heat to plants and vegetables, and is the first mover of all their actions; by the genial heat which it affords, and its influence upon the soils, it promotes the growth of them all.

Plants, therefore, which in their growth are more or less exposed to the sun, are, for the most part, more prosperous, forwarder, and attain greater perfection than such as grow in any considerable shade: and most fruits in a sunny exposure are considerably more beautiful, sooner ripe, and acquire superior quality in flavour, &c. to those growing in shady places: and as it has a highly fertilizing effect upon the earth, the ground designed to be mellowed should always be turned up in rough ridges, to give free access to the influence of the sun and air; likewise all compost heaps should generally be prepared in sunny situations, in the full air, not in shady corners, or in sheds, as is often practised by gardeners.

SWIETENIA, a genus furnishing a plant of the exotic tree kind for the stove.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Trihilatae*.

The characters are: that the calyx is a one-leaved perianth, five-cleft, obtuse, very small, deciduous: the corolla has five petals, obovate, obtuse, concave, spreading: nectary one-leaved, cylindric, length of the petals, mouth ten-toothed: the stamina have ten filaments, very small, inserted below the teeth of the nectary: anthers oblong, erect: the pistillum is an ovate germ: style awl-shaped, erect, length of the nectary: stigma headed, flat: the pericarpium is an ovate capsule, large, woody, one-celled, at the top five-celled, five-valved, valves opening at the base: the seeds very many, imbricate, compressed, oblong, obtuse, having a leafy wing: receptacle large, five-cornered.

The species cultivated is *S. Mahagoni*, Mahogany Tree.

In its native state it is a lofty and very branching tree, with a wide handsome head; the leaves reclining, alternate, shining, eight inches long, numerous on the younger branches: leaflets for the most part four pairs, but often three, seldom five, without any odd one, falcate-lanceolate, quite entire, acuminate, bent in backwards, petioled, opposite, an inch and half long: the racemes subcorymbed, with about eight flowers in each, axillary, solitary, two inches long; the flowers are small, whitish; the capsule large, (sometimes attaining the size of a child's head,) woody, ovate, of a smoky-rufescent colour (or ferruginous), towards the top five-celled, but in other parts widely one-celled, five-valved: valves thick, opening from the base, caducous, covered within by a thick flexible coriaceous lamina, exactly equal to them in size. A native of the warmest parts of America, &c.

Culture.—This plant may be increased by sowing the seeds obtained from abroad in small pots, filled with light sandy mould, in the spring, plunging them in a hot bed, and watering them occasionally: when the plants are a few inches high, they should be carefully removed into other pots separately, replunging them in the hot-bed, giving them shade till re-rooted; they should afterwards have the management of other stove plants. They afford variety and curiosity in stove collections.

SYMPHYTUM, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Asperifoliae*.

The characters are: that the calyx is a five-parted perianth, erect, five-cornered, acute, permanent: the corolla one-petalled, bell-shaped: tube very short: border tubular-bellied, a little thicker than the tube: mouth five-toothed, obtuse, reflexed: throat fenced by five lanceolate rays, spinulose at the edge, shorter than the border, converging into a cone: the stamina have five awl-shaped filaments, alternate with the rays of the throat; anthers acute, erect, covered; the pistillum is as four germs: style filiform, length of the corolla: stigma simple: there is no pericarpium: calyx larger, widened: seeds four, gibbous, acuminate, converging at the tips.

The species cultivated are: 1. *S. officinale*, Common Comfrey: 2. *S. tuberosum*, Tuberous-rooted Comfrey, 3. *S. orientale*, Oriental Comfrey.

The first has a perennial root, fleshy, externally black; the stem two or three feet high, upright, leafy, winged, branched at the top, clothed with short bristly hairs that point rather downward: the leaves waved, pointed, veiny, rough; the radical ones on footstalks, and broader than the rest; the clusters of flowers in pairs on a common stalk, with an odd flower between them, recurved, dense, hairy: the corolla yellowish-white, sometimes purple: the rays downy at each edge. It is a native of Europe and Siberia.

There are varieties with white flowers, purple flowers, with blue flowers, and with red flowers.

The second species has the roots composed of many thick fleshy knobs or tubers, which are joined by fleshy fibres: the stalks rise a foot and half high, and incline on one side: the leaves on the lower part are six inches long, and two inches and a half broad in the middle, ending in acute points, and not so rough and hairy as the first; they are alternate and sessile: the two upper leaves on every branch stand opposite, and just above them are loose bunches of pale yellow flowers, the corolla of which is stretched out further beyond the calyx than in the com-

Yellow Sarracena

mon sort. It is a native of Germany, &c., and flowers from May to October.

The third has a perennial root: the stalks two feet high: the leaves rounder, and armed with rough prickly hairs: the flowers in bunches like the first sort, but blue: they appear in March, but seldom produce seeds in this climate. Found near Constantinople.

Culture.—These plants may be increased by seeds or parting the roots, but the latter is more practised. The seeds should be sown in the spring, in a border of common earth; in the autumn the plants will be proper to set out where they are to remain, or to remove into other pots. The roots should be parted in the autumn, and planted out either in beds about a foot from plant to plant, or where they are to remain; almost every part will grow, and the plants are hardy, and succeed in any soil or situation: they only require to be kept clean afterwards. They produce variety in mixture in the borders.

SYRINGA, a genus containing plants of the deciduous flowering shrubby kind.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Sepiaria*.

The characters are: that the calyx is a one-leaved perianth, tubular, small: mouth four-toothed, erect, permanent: the corolla one-petalled, funnel-form: tube cylindric, very long: border four-parted, spreading and rolled back: segments linear, obtuse: the stamina have two filaments, very short: anthers small, within the tube of the corolla: the pistillum is an oblong germ: style filiform, length of the stamens: stigma bifid, thickish: the pericarpium is an oblong capsule, compressed, acuminate, two-celled, two-valved: valves contrary to the partition: the seeds solitary, oblong, compressed, acuminate at both ends, with a membranaceous edge.

The species cultivated are: 1. *S. vulgaris*, Common Lilac: 2. *S. Persica*, Persian Lilac.

The first is a shrub, which grows to the height of eighteen or twenty feet in good ground, and divides into many branches; those of the White sort grow more erect than the Blue; and the Purple or Scotch Lilac has its branches yet more diffused. The branches of the White are covered with a smooth bark of a gray colour; in the other two it is darker; the leaves of the White are of a brighter green; they are heart-shaped in all, almost five inches long, and three inches and a half broad near the base, placed opposite, on foot-stalks an inch and half in length. The buds of the future shoots, which are very turgid before the leaves fall, are of a very bright green

in the White sort, but those of the other two are dark green. The flowers are always produced at the ends of the shoots of the former year; and below the flowers other shoots come out to succeed them; as that part upon which the flowers stand decays down to the shoots below every winter. There are generally two bunches or panicles of flowers joined at the end of each shoot; those of the Blue are the smallest, the flowers also are smaller, and placed thinner than either of the others; the bunches on the White are larger, but those of the Scotch are larger still, and the flowers fairer; it of course makes the best appearance: the panicles of flowers grow erect, and, being intermixed with the bright green leaves, have a fine effect, which with the fragrant of the flowers, renders it one of the most beautiful shrubs of the garden: the flowers appear early in May, or towards the end of April, and when the season is cool continue three weeks; but in hot seasons soon fade. It is supposed a native of Persia.

There are several varieties: as with white flowers, with blue flowers, with purple flowers, or Scotch Lilac.

The second species is a shrub of much lower growth than the common sort, seldom rising more than five or six feet high: the stems are covered with a smooth brown bark: the branches are slender, pliable, extend wide on every side, and frequently bend down where they are not supported: the leaves two inches and a half long, and three fourths of an inch broad, of a deep green colour: the flowers in large panicles at the end of the former year's shoots, as in the former; of a pale blue colour, and having a very agreeable odour. They appear at the end of May, soon after those of the common sort, and continue longer in beauty, but do not perfect their seeds in this climate.

There are several varieties: as the common purple-flowered, white-flowered, blue-flowered, and the lacinated or cut-leaved.

Culture.—These plants are mostly raised by suckers or layers, and sometimes by seeds. The suckers should be taken off in the autumn or spring, with root-fibres to them, and be planted out either in nursery-rows, to remain a year or two, or where they are to remain. The layers may be made from the young pliant shoots, and be laid down in the autumn, in the usual way, when in the autumn following they may be taken off and planted out, as in the suckers. The first sort may likewise be raised from seeds sown in a bed of common earth, in the autumn or spring, keeping the plants clean when they come up. They afford variety in the large borders and other parts of shrubberies.

TABERNÆMONTANA, a genus containing plants of the woody exotic and hardly perennial kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Contortæ*.

The characters are: that the calyx is a five-cleft perianth, acute, converging, very small: the corolla one-petalled, funnel-form; tube cylindric, long; border five-parted, flat; segments obtuse, oblique: nectary glands five, bifid, standing round the germ: the stamina have five filaments, very small, from the middle of the tube: anthers converging: the pistillum has two simple germs; style awl-shaped; stigma oblong, headed: the pericarpium has two follicles, horizontally reflexed, ventricose, acuminate, one-celled, one-valved: the seeds numerous, ovate-oblong, obtuse, wrinkled, immersed in pulp, imbricate.

The species cultivated are: 1. *T. citrifolia*, Citron-leaved Tabernæmontana; 2. *T. laurifolia*, Laurel-leaved Tabernæmontana; 3. *T. Amsonia*, Virginian Tabernæmontana; 4. *T. angustifolia*, Narrow-leaved Tabernæmontana.

The first rises with an upright woody stalk, to the height of fifteen or sixteen feet, covered with a smooth gray bark, abounding with a milky juice, and sending out several branches from the side, which grow erect, and have many joints: the leaves are thick, milky, from five to six inches long, and two inches broad in the middle, drawing to a point at each end; they are of a lucid green, have many transverse veins, and stand opposite on footstalks an inch long: the flowers come out in roundish axillary bunches; they are small, of a bright yellow colour, and have an agreeable odour. It is a native of Jamaica, Martinico, &c.

The second species rises with a shrubby stalk twelve or fourteen feet high, sending out a few branches towards the top, which grow erect: the leaves are four inches long and two broad, of a lucid green colour: the flowers are produced in a sort of umbel from the side of the branches; are small, yellow, and have an agreeable odour. It is a native of Jamaica, St. Domingo, &c.

The third is a perennial plant, sending up in the spring two or three herbaceous stalks near a foot high: the flowers are produced in small terminating bunches, white and void of scent. It is a native of North America, flowering in May and June.

The fourth species is a perennial plant, native of North America, flowering in May and June.

Culture.—These plants may be increased by seeds, which must be procured from the countries where the plants grow naturally, and be sown early in the spring on a hot-bed; and when the plants are come up, and fit to remove, be carefully planted out into small pots filled with light rich earth, and then plunged into a hot-bed of tanner's bark, being careful to shade them in the heat of the day until they have taken new root; after which they should have free air admitted to them every day when the weather is warm; but on cold nights have the glasses of the hot-bed covered with mats every evening, soon after the sun goes off from the bed: they must be often refreshed with water, but not in large quantities, especially while they are young, as they are full of a milky juice, and are subject to rot with much moisture: they may remain during the summer season in the hot-bed, by stirring up the tan to renew the heat when it wants, and a little new tan being added; but when the nights begin to be cold, the plants should be removed, and plunged into the bark-bed in the stove, where, during the winter season, they must be kept in a moderate degree of warmth, and in cold weather have but little water given them: they should constantly remain in the stove, where, in warm weather, they may have free air admitted to them by opening the glasses, but in cold weather be kept warm. With this management they thrive and produce flowers; and, as their leaves are always green, make a pleasant diversity among other tender exotic plants: they may be increased likewise by cuttings in the summer season, which should be cut off from the old plants, and laid to dry in the stove five or six days before they are planted, that the wounded parts may heal over: these should then be planted in pots filled with fresh light earth, and plunged into the hot-bed of tanner's bark, and closely covered with a hand-glass, shading them from the sun in the middle of the day in hot weather, refreshing them now and then with a little water: when they have taken root, they may be planted out into separate pots, and be treated in the same manner as those raised from seeds.

The third and fourth sorts are capable of living in the open air here, provided they are planted in a warm situation; they love a light soil, rather moist than otherwise; of course, when planted in dry ground, they should be frequently watered

reased by off-sets
be planted out in
society in the stove,
as well as the borders.

h pale-yellow or

brimstone-coloured flowers, with deep yellow
flowers, with orange-coloured flowers; each
with single, double, and fistulous flowers; the
middling African, with orange-coloured flowers,
and the sweet-scented African.

Culture.—These plants are increased by seeds,
which should be sown in the beginning of
April upon a hot-bed, and when the plants ap-
pear, they should have plenty of fresh air, and
after they have attained some growth be trans-
planted on to another hot-bed, which is arched
over by hoops, at the distance of six inches,
watering and shading them well till fresh rooted,
being afterward gradually inured to the open
air; and about the beginning of May they may
be taken up with balls of earth about their roots,
and planted in pots, to be set out in the courts,
yards, &c., about the house, shading them till
fresh rooted, and giving them water occa-
sionally: but the first sort divides and spreads
out widely near the ground, in a rambling man-
ner, and requires to be trimmed up at bot-
tom to a single stem, and its branches occa-
sionally, to preserve the head somewhat regular,
and within due bounds.

The second species in particular, and the va-
rieties, as they always grow firmly erect, both
in stem and branches, require but very little
trouble after their final planting out: they afford
ornament and variety among other plants, in
the borders, clumps, and other parts of pleasure-
grounds, as well as in pots for particular places
about the house, among other potted annual
plants. The seeds of each species, and their
varieties, should be annually saved from the
best plants.

TALLOW TREE. See CROTON.

TAMARINDUS, a genus containing a plant
of the exotic tree kind.

It belongs to the class and order *Monadelphia*
Triandria, (*Triandria Monogynia*,) and ranks
in the natural order of *Lomentaceæ*.

The characters are: that the calyx is a one-
leafed perianth; tube turbinate, compressed,
attenuated below, permanent; mouth oblique;
border four-parted, deciduous; segments ovate,
acute, flattish, reflexed, coloured; the upper
and lower a little wider: the corolla has three
petals, ovate, concave, acute, crenate, waved,
reflexed, length of the calyx, inserted into the
mouth of the tube, the two lateral ones a little
larger: the stamina have three filaments, in-
serted into the orifice of the calyx at the void
sinus, length of the corolla, awl-shaped, united
below up to the middle, bowed towards the co-
rolla: anthers ovate, incumbent, large: threads
five (rudiments of stamens), alternate with the
filaments, and united below, but separate above,

bristle-shaped, headed, very short; the two lateral ones lower than the others; bristles two, springing from the calyx below the filaments, and incumbent on them, very small: the pistillum is an oblong germ, compressed, curved in, placed on a pedicel fastened to the bottom of the calyx, and growing longitudinally to its tube under the back, beyond the tube, with the upper margin villose: style awl-shaped, ascending, pubescent on the lower margin, a little longer than the stamens: stigma thickened, obtuse: the pericarpium is a legume, oblong, compressed, blunt with a point, swelling at the seeds, covered with a double rind, the outer dry and brittle, the inner membranaceous; a soft pulp between both; one-celled, not opening: the seeds few, angular-roundish, plano-compressed, shining, hard.

The species is *T. Indica*, Tamarind-tree.

It grows to a very large size in the countries where it is a native: the stem is very large, covered with a brown bark, and divides into many branches at the top, spreading wide every way; the leaves pinnate, composed of sixteen or eighteen pairs of leaflets, without a single one at the end; they are about half an inch long, and a sixth part of an inch broad, of a bright green, a little hairy, and sit close to the midrib: the flowers come out from the side of the branches, five, six, or more together, in loose bunches; the pods are thick and compressed; those from the West Indies from two to five inches in length, with two, three, or four seeds; those from the East Indies are almost twice as long, and contain five, six, and even seven seeds. It is a native of both the Indies, &c.

Culture.—This plant is increased from seeds, which should be sown in the spring on a hot-bed, and when the plants are come up, each planted in a separate small pot filled with light rich earth, plunging them into a hot-bed of tanner's bark to bring them forward, watering and shading them until they have taken root; and as the earth in the pots becomes dry, they must be watered from time to time, and have air given in proportion to the warmth of the season, and the bed in which they are placed: when the pots in which they are planted are filled with their roots, the plants should be shifted into pots of a larger size, which must be filled up with rich light earth, and again plunged into the hot-bed, giving them air as before, according to the warmth of the season; but in very hot weather the glasses should be shaded with mats in the heat of the day, otherwise the sun will be too violent for them through the glasses; nor will the plants thrive if they are exposed to the open air, even

in the warmest season; so that they must be constantly kept in the bark-stove both summer and winter, treating them in the same manner as the Coffee-tree. These plants have a good effect in the stove collections.

TAMARIX, a genus furnishing plants of the hardy, deciduous, tree, and shrub kinds.

It belongs to the class and order *Pentandria Trigynia*, and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is a five-parted perianth, obtuse, erect, permanent, shorter by half than the corolla: the corolla has five petals, ovate, concave, obtuse, spreading: the stamens have five capillary filaments: anthers roundish: the pistillum is an acuminate germ: style none: stigmas three, oblong, revolute, feathered: the pericarpium is an oblong capsule, acuminate, three-sided, longer than the calyx, one-celled, three-valved: the seeds very many, very small, papose.

The species cultivated are: 1. *T. Gallica*, French Tamarisk; 2. *T. Germanica*, German Tamarisk.

The first in its native situation grows to a tree of middling size, but in this climate seldom more than fourteen or sixteen feet high: the bark is rough, and of a dark brown colour: it sends out many slender branches, most of which spread out flat and hang downward at their ends; these are covered with a chesnut-coloured bark, and garnished with very narrow finely divided leaves, which are smooth, of a bright green colour, and have small leaves or indentures which lie over each other like scales of fish: the flowers are produced in taper spikes at the end of the branches, several of them growing on the same branch: the spikes are about an inch long, and as thick as a large earth-worm: the flowers are set very close all round the spike, are very small, and have five concave petals of a pale flesh colour, with five slender stamina terminated by roundish red anthers: they appear in July. It is a native of the South of France, &c.

The second species is rather a shrub than a tree, having several woody stalks arising from the same root, which grow quite erect, sending out many side branches which are also erect; they have a pale-green bark when young, afterwards changing to a yellowish colour: the leaves are shorter, and set closer together than those of the first sort, and are of a lighter green, approaching to a gray: the flowers are produced in long loose spikes at the end of the branches, standing erect, and are larger than those of the first. It is a native of Germany, &c.

Culture.—These plants may be increased either by laying down their tender shoots in

T A M

autumn, or by planting cuttings in an east border, which will take root in a short time, if they are supplied with water in the spring, before they begin to shoot in dry weather; but they should not be removed until the following autumn, at which time they may be either placed in a nursery to be trained up two or three years, or where they are designed to remain, mulching their roots, and watering them according as the season requires, until they have taken root; after which, the only culture they will require, is to prune off the straggling shoots, and keep the ground clean about them.

The layer method is not only tedious but unnecessary, as the cuttings grow readily, and the layers often will not strike at all. The cuttings should be of the last summer's shoots, and a moist border is most proper for them. In two years they will be good plants for the shrubbery, and may be planted out in almost any soil, though they like a light moist earth best, especially the latter sort, which grows naturally in low watery situations.

They are very ornamental in the shrubbery borders, clumps, and other parts of grounds.

TAMUS, a genus furnishing plants of the hardy herbaceous climbing perennial kind.

It belongs to the class and order *Dioecia Hexandria*, and ranks in the natural order of *Sarmentaceae*.

The characters are: that in the male, the calyx is a six-parted perianth: leaflets ovate-lanceolate, spreading more at top: there is no corolla: the stamina have six simple filaments, shorter than the calyx: anthers erect: female—calyx a one-leafed perianth, six-parted, bell-shaped, spreading: segments lanceolate, superior, deciduous: the corolla petals none: nectaries an oblong point, fastened internally to each calycine segment at the base: the pistillum is an ovate-oblong germ, large, smooth, inferior: style cylindrical, length of the calyx: stigmas three, reflexed, emarginate, acute: the pericarpium is an ovate berry, three-celled: the seeds two, globular.

The species are: 1. *T. Communis*, Common Black Bryony; 2. *T. cretica*, Cretan Black Bryony.

The first has a very large tuberous root, blackish externally, whence its old Latin and English names: the stems smooth, twining about every thing in their way, and thus ascending, without the aid of tendrils, to the height of ten or twelve feet in hedges or among bushes, which their festoons of tawny leaves and red berries decorate in autumn: the leaves alternate, petioled, smooth and shining, quite entire; the nerves raised beneath, varying from kidney- to

T A N

heart-shaped, heart-spear-shaped, triangular spear-shaped, and even halbert-shaped: the flowers greenish, in long racemes or bunches from the side of the stalks, appearing in June; the barren and fertile ones on separate roots. It is a native of Europe.

The second species has a rounder root than the other; the stalks twine in the same manner; but the principal difference consists in the leaves being divided into three lobes. It was discovered in the island of Crete or Candia.

Culture.—These plants are readily increased by sowing the seeds soon after they are ripe under the shelter of bushes, where, in the spring, the plants will come up, and require no further care; or in beds to be afterwards planted out. The roots will abide many years, and sometimes send up suckers, from which plants may be raised by setting them out in the autumn or spring where they are to remain.

They are useful in thickets and wilderness parts. TAN. See BARK.

TANACETUM, a genus furnishing plants of the herbaceous and shrubby perennial kinds.

It belongs to the class and order *Syngenesia Polygamia Superflua*, and ranks in the natural order of *Compositae Discoideae*.

The characters are: that the calyx is common hemispherical, imbricate: scales acute, compact: the corolla compound tubular, convex: corollets hermaphrodite numerous, tubular, in the disk; females some in the ray: proper of the hermaphrodite funnel-form; with a five-cleft reflexed border: female trifid, more deeply divided inwardly: the stamina in the hermaphrodites: filaments five, capillary very short: anther cylindric, tubular: the pistillum in the hermaphrodites germ oblong, small: style filiform, length of the stamens: stigma bifid, revolute; in the females germ oblong: style simple: stigmas two, reflexed: there is no pericarpium: calyx unchanged: the seeds solitary, oblong: down slightly margined: the receptacle convex, naked.

The species cultivated are: 1. *T. vulgare*, Common Tansy; 2. *T. annuum*, Annual Tansy; 3. *T. Balsamita*, Cost-mary; 4. *T. Sibiricum*, Siberian Tansy; 5. *T. suffruticosum*, Shrubby Tansy; 6. *T. flabelliforme*, Fan-leaved Tansy.

The first has a fibrous creeping root, which will spread to a great distance: the herb is bitter, and has a strong aromatic smell: the stems upright, two feet high, (in a garden from two to almost four feet,) leafy, round, striated, scarcely hairy: the leaves alternate, deep green, acutely cut, smooth, or somewhat hairy beneath, cared at the base, embracing: pinnules lanceolate deeply and acutely serrate: the flowers are in

terminating corymbs, of a golden colour and flatish. It is a native of Europe and Siberia, flowering from June to August.

There are varieties with curled leaves, called Double Tansy; with variegated leaves; and with larger leaves, which have little scent.

The second species is an annual plant, rising about two feet high: the stem stiff, but herbaceous, sending out many side branches their whole length; the lower ones four or five inches long, gradually shorter to the top: the leaves come out in small clusters from the joints; they are very narrow and short; some end in three points, others are single: the branches are terminated by clusters of flowers of a bright yellow; each corymb on a short peduncle. They appear in July or August, and continue till the frost destroys them. It has a fine aromatic scent, and is a native of Spain and Italy.

The third has a hardy root, fleshy and creeping: the lower leaves near three inches long, and an inch and half broad, of a grayish colour, and on long footstalks: the stems rise from two to three feet high, and send out branches from the side: the leaves on these are like the lower ones, but smaller and sessile: the flowers are produced at the top of the stems in a loose corymb; they are naked, and of a deep yellow colour, appearing in August. The whole plant has a soft pleasant odour. It is a native of the South of France, Spain, and Italy.

The fourth species has the leaves linear, pinnate: pinnae linear, filiform, often bifid or trifid, quite entire: the corymb terminating and others axillary, few-flowered; flowers yellow: the root is fibrous perennial: the stalks more than two feet high. It flowers in June and July, and is a native of Siberia.

The fifth species rises with a branching shrubby stalk, three or four feet high: the segments of the leaves are very narrow, and frequently cut into acute segments: the flowers are produced in small roundish bunches, at the ends of the branches, of a bright yellow, and appear in August. It is a native of the Cape.

The sixth species has all the florets hermaphrodite and five-cleft: the receptacle naked, not chaffy. It is a native of the Cape, flowering from May to August.

Culture.—The different herbaceous species are increased by parting the roots, and by seed.

In the first mode the business is effected by slipping or dividing the roots in autumn or winter, when the stalks are decayed; or early in spring, before new stalks shoot forth, planting the slips at once where they are to remain; those for the kitchen-garden, as the Common Tansy, &c. in any bed or border a foot and a half

asunder; and those intended for variety in the pleasure-ground, singly here and there, at suitable distances, to effect a proper diversity.

The seed sowed in autumn should be sown in the spring following, in beds of light earth, broad-cast and raked in, when the plants will soon come up, and in July be fit to prick out in beds, in rows a foot asunder; some to remain, and others to be planted out in autumn where they are to grow.

The shrubby sorts are easily increased by cuttings of the branches, which should be planted any time in spring and summer, choosing the young and most robust shoots, which should be cut off in proper lengths; and if early in spring, &c. be planted in pots of good earth, several in each, plunging them in a hot-bed, where they will be rooted, and fit for potting off separately in six weeks; or, if in summer, the young shoots may be planted in the full ground, in a shady border, or where they may be shaded with mats from the sun; or in pots, and placed in the shade, or under a garden frame, &c.; in all of which methods, giving plenty of water, they will readily take root; but those in the hot-bed will be forwardest: they however will all be well rooted the same season, and should then be transplanted in separate pots, and managed as other shrubby green-house plants. See GREEN-HOUSE PLANTS.

The former sorts require to be afterwards kept free from weeds, cutting down the decayed stalks annually in autumn; and as the roots increase fast into large bunches, spreading widely round, they should be cut in, or be slipped occasionally, otherwise they are apt to overrun the ground; and to have the ground dug between the plants annually.

The latter sorts are somewhat tender, but only require shelter from frost, being kept in pots, and deposited among the green-house plants, and treated as other shrubby exotics of that collection. They effect a very agreeable variety at all times of the year, but particularly in summer and autumn, when in flower.

TARCHONANTHUS, a genus containing a plant of the shrubby evergreen exotic kind.

It belongs to the class and order *Syngenesia Polygamia Aequalis*, and ranks in the natural order of *Nucamentaceæ*.

The characters are: that the calyx is common turbinate, one-leaved, commonly half-seven-cleft, coloured internally, shorter than the corolla, sharpish, permanent: the corolla compound uniform: florets about twenty: corollets hermaphrodite, numerous, equal: proper one-petalled, funnel-form, five-toothed: the stamina have five filaments, capillary, very

short: anther cylindric, tubular, length of the corollet, tailed at the base: the pistillum is a superior germ, oblong: style twice as long as the flower: stignias two, gaping: there is no pericarpium: calyx unchanged: the seeds solitary, oblong: down hairy, investing the seed all round: the receptacle hairy, very small, hairs length of the calyx.

The species cultivated is *T. camphoratus*, Shrubby African Fleabane.

It has a strong woody stem, rising to the height of twelve or fourteen feet, sending out many woody branches at the top, which may be trained to a regular head: the leaves are in shape like those of the Broad leaved Sallow, having a downy surface like Sage, and their under sides white; in smell they resemble Rosemary leaves when bruised: the flowers are produced in spikes at the extremity of the shoots, but, being of a dull purple colour, do not make much show: they appear in autumn, and continue great part of the winter. It retains its leaves all the year, and is a native of the Cape.

Culture.—This plant may be increased by cuttings, which should be planted out in the spring or early summer seasons in pots filled with light mould, giving them shade and water occasionally. They soon strike root, and in three or four months may be potted off into separate pots, affording them shade and water as before, and placing them under shelter. They also strike root in the summer season when planted in a common border and covered with hand-glasses, and may in these cases be potted off in the autumn.

They afterwards require the management of other hardy green-house plants.

They afford variety in these situations.

TARRAGON. See ARTEMISIA.

TAXUS, a genus furnishing a plant of the hardy evergreen tree kind.

It belongs to the class and order *Dioecia Monadelphica*, and ranks in the natural order of *Coniferae*.

The characters are: that in the male there is no calyx, except a bud like a four-leaved perianth: corolla none: the stamina have numerous filaments, united at bottom into a column, longer than the bud: anthers depressed, blunt at the edge, eight-cleft, gaping every way at the base, and, when they have discharged their pollen, flat, peltate, and remarkable for their eight-cleft margin: female—the calyx as in the male: corolla none: the pistillum is an ovate-acuminate germ: style none: stigma obtuse: the pericarpium is a berry from the receptacle, elongated into a præputium globular, succulent, gap-

ing at the top, coloured, at length wasting from dryness, and evanescent: the seed one, ovate-oblong, prominent at the top, beyond the berry.

The species cultivated is *T. baccata*, Common Yew-tree.

It has a straight trunk, with a smooth deciduous bark: the wood very hard, tough, and of a fine grain: the leaves thickly set, linear, smooth, evergreen: the flowers axillary, enveloped with imbricate bractes: the male on one tree, sulphur-coloured, without a calyx: the female on another, with a small green calyx, sustaining the oval flattish seed; which calyx at length becomes red, soft, and full of a sweet slimy pulp. It is a native of Europe, North America, &c.

It varies with very short leaves, with broad shining leaves, and with striped or variegated leaves.

Culture.—In this tree the increase may be effected by seeds, and sometimes by layers and cuttings.

After having procured a quantity of the Yew berries, and divested them of the pulp or mucilage, they should be sown in beds of light earth, either in shallow drills, or scattered over the surface, in the autumn or spring season (but the former is the best method, as the plants rise in the following spring), and be covered near an inch deep with light mould, out of the alleys, &c. They require no further care, only to keep the beds clean from weeds before and after the plants come up, and to give occasional waterings in dry weather, in spring and summer, to forward and strengthen the plants in their growth. They should have two years' growth in the seed-bed; then in the autumn or spring be planted out upon four-foot-wide beds, in nursery-rows, a foot asunder, to remain two, three, or four years, when some may be planted out finally for hedges, where required; others in the nursery quarters, in rows, two or three feet asunder, to be trained in a suitable manner for the purposes they are intended.

After growing in the nursery till they obtain from half a yard to four or five feet stature, they may be finally planted out in autumn or spring, for their intended purposes; when they will rise with a large spread of roots. They should be planted in their places as soon after removal as possible, giving each plant a good watering at the time.

In the future culture, those trained in hedges, &c. must be clipped annually, once or twice in the summer; and those in the shrubberies and rural plantations have the lower branches pruned up occasionally to a single stem; but the head

should generally be permitted to spread agreeably to its natural mode of growth, except just reducing any considerable rambling branch, &c.

The Striped or Variegated Yews, and other varieties, should be increased by layers or cuttings, as they are rarely permanent by seeds.

The layers should be made from the young shoots of not more than a year or two old, being laid down in spring, summer, or early in autumn, when many of them will take root, and in one or two years be fit for planting off into nursery-rows.

The cuttings should be made by cutting or slipping off a quantity of the one-year's shoots, divesting them of the lower leaves, and planting them in a shady border thick together, in small trenches, in the early spring or autumn, giving water at planting, and afterwards occasionally in dry hot weather. They will be well rooted in two years, and fit for being planted out into wide nursery-rows.

These plants may be employed as ornamental evergreens and as forest-trees; and they were formerly much used in hedges and trained figures: they have a good effect in shrubberies among others of the evergreen tribe, being permitted to assume their natural growth, in common with other trees and shrubs; and when planted as detached standards, in extensive distant opens of grass-ground, in parks, and the sides of hills, &c. likewise when introduced as forest-trees in timber plantations of the evergreen-kind. See PLANTATION.

For hedge-work, where internal hedges are required, either for ornament or shelter, no tree is better calculated, from its forming the closest, even, moderate-growing hedge of any tree of the evergreen collection. It is also calculated for training into formal or fancy figures, both in hedge-work and as detached objects, from its branches and leaves growing exceedingly close, and shooting very moderately and with regularity.

For these purposes the trees should be trained in their minor growth in the nursery; if for hedges or any fancy figures, by suffering the plants to branch away immediately from the very bottom, and cutting them with garden shears once or twice every summer; and if for the shrubbery or other rural plantations, by pruning them up a little at bottom to a single stem, and suffering the heads to branch out on all sides and at top diffusively; likewise, if for larger detached standards, by trimming up the stems gradually to elevate them in proportion, and encourage the heads to branch out, and spread widely.

TELEPHIUM, a genus furnishing a plant of the small hardy perennial kind.

It belongs to the class and order *Pentandria Trigynia*, and ranks in the natural order of *Portulacaceæ*.

The characters are: that the calyx is a five-leaved perianth: leaflets oblong, obtuse, concave, keeled, length of the corolla, permanent: the corolla has five petals, oblong, obtuse, narrower below, erect, inserted into the receptacle; the stamina have five awl-shaped filaments, shorter than the corolla: anthers incumbent: the pistillum has a three-sided acute germ: style none: stigmas three, acute, spreading: the pericarpium is a short capsule, three-sided, three-valved, one-celled: the receptacle free, shorter by half than the capsule: seeds very many, roundish.

The species cultivated is *T. Imperati*, True Orpine.

It has a root composed of yellowish woody fibres, spreading out wide: the stalks and branches are slender, trailing, eight or nine inches long: the leaves small, ovate, grayish, smooth and pretty stiff, having one longitudinal nerve running through the middle: the flowers terminating, in short thick bunches, or corymbs, reflexed, of a white colour. It is a native of the South of France, Spain, &c. flowering from June to August.

Culture.—This plant is increased by sowing the seeds in the autumn or spring, in dry light mould, either where the plants are to remain, or in beds to be afterwards planted out. They appear in the spring, when they should be kept clear from weeds, and they will flower the following year.

It is also capable of being increased sometimes by offsets, slips, or cuttings, planted out in the spring season.

The plants afford variety in the common borders and clumps.

TEA-BUCKTHORN. See RHAMNUS.

TEA, NEW JERSEY. See CEANOTHUS.

TEA, NEW ZEALAND. See PHILADELPHUS.

TEA, OSWEGO. See MONARDA.

TEA TREE. See THEA.

TEA, WEST INDIAN. See SIDA.

TERRACE, a sort of raised bank of earth, &c. regularly formed in an oblong manner to any length, broad enough to admit of a spacious level walk at top, and elevated considerably above the level of the general surface; having the sides uniformly sloped; and laid with grass, and the top formed into a flat or level, sufficiently broad for a grass or gravel walk, of pro-

portionable width; designed in gardens as a high, airy walk, to command a better prospect of the adjacent places around, within and without the garden occasionally, as well as to enjoy the fresh air in summer more freely. In the former style of laying out gardens, it was considered as very ornamental, but is at present much in disuse.

The height of a Terrace-walk may be more or less as the situation admits, as from one foot to one or two yards; or even three or four yards or more in particular situations, and where there are plenty of earthy materials, rubbish, &c. to form it, allowing breadth in proportion, from five to ten or twenty feet or more, and extended to any length required. They are sometimes formed on some naturally high, rising ground, to save as much trouble as possible, in bringing stuff from a distance; and sometimes raised wholly of forced materials.

The situation for a Terrace may be varied as the natural situation of the place may require.

In respect to form, they should always be broader at the base than the top, and extend lengthways to any distance required; having the sides regularly sloped, of more or less acclivity, as the width, height, and situation admit. Sometimes both sides are sloped, and sometimes only one side, the other perpendicular, and faced with a substantial wall, &c. or formed against the side of a hill, or some naturally rising ground; being finished always broad enough at top to admit of a proper walk. In some naturally-elevated situations, Terraces are sometimes formed one above another in two or more ranges, each having its separate side slopes, and elevated walk; in all of which the slopes are to be neatly laid with grass, and the walk at top occasionally of grass or gravel.

The entrances leading to Terrace-walks were formerly sometimes formed by an easy acclivity of a grass or gravelled slope, and sometimes by a grand flight of stone steps.

Where a rising ground, of considerable elevation, naturally presents itself in a proper situation, it is an eligible opportunity for forming a Terrace with the least expense and trouble, on account of its not requiring the addition of so much earth and rubbish as when raised entirely on a perfect level, wholly of made earth.

Where there are any excavations of ground intended to form ha-has, pieces of water, &c. the excavated earth may be employed in forming Terraces, &c.

In the forming of a Terrace, the base must be staked out wider than the intended width at top for the walk, in order to admit of the ascent of slopes being moderate. And the whole of

the made earth and rubbish must be well rammed and rolled down from time to time as it is applied, in order to render the whole equally firm, that it may not settle irregularly after being finished. The slopes may either be laid with turf, or sown with grass-seeds; but the first is much the best method where it can be employed. See GRASS-GROUND.

TETRAGONIA, a genus containing plants of the shrubby and herbaceous succulent perennial kinds.

It belongs to the class and order *Icosandria Pentagynia*, and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is a four-leaved perianth, superior: leaflets four, ovate, bent down and flat, rolled back at the edge, coloured, permanent: there is no corolla, unless the calyx be called so: the stamina have twenty filaments, capillary, shorter than the calyx: anthers oblong, incumbent: the pistillum is a roundish germ, five-cornered, inferior: styles four, awl-shaped, recurved, length of the stamens: stigma longitudinal of the style, pubescent: the pericarpium is a coriaceous drupe, four-cornered with four longitudinal wings; the opposite angles narrower, not opening: the seed one, bony, four-celled: kernels oblong.

The species cultivated are: 1. *T. fruticosa*, Shrubby Tetragonia; 2. *T. decumbens*, Trailing Tetragonia; 3. *T. herbacea*, Herbaceous Tetragonia; 4. *T. echinata*, Hedge-hog Tetragonia.

The first has slender woody stems, rising three or four feet high if supported, otherwise trailing, covered with a light gray bark, and dividing into a great number of trailing branches, which when young are succulent, of an herbaceous colour, and covered with small pellucid drops, which reflect the light, somewhat like the Diamond Ficoides: as the branches grow older, they become more woody: the leaves are narrow, thick, succulent, about half an inch long, and a tenth of an inch broad, concave and blunt-pointed; they are placed alternately, and at their base comes out a cluster of smaller leaves, which have the like pellucid drops with the stalks: the flowers axillary, at every joint towards the ends of the branches, solitary, or two or three together. The fruit is an inferior juiceless drupe.

The second species has larger stalks than the preceding, but they branch out in like manner: the branches trail upon the ground; the young branches are very succulent, and almost as thick as a man's little finger: the leaves are two inches long, and an inch broad; their surface covered with very small pellucid drops, as are also the young branches: flowers larger, upon pretty

long footstalks, three or four from the same point: the calyx and anthers are of a pale sulphur colour. It flowers from July to September.

The third has large fleshy roots: the branches weak and trailing, generally decaying about midsummer, and new shoots produced late in autumn: the leaves come out in bunches; they are oval, plane, and not so thick and succulent as in the other sorts; they are little more than an inch long, and half an inch broad: the flowers are produced from the wings of the leaves in February; they are like those of the second sort, and have long slender footstalks. It flowers in June and July.

The fourth species has a biennial root: the stem herbaceous, near the root dividing into diffused branches, rendered angular by the petioles running down them, scarcely a foot long: the leaves succulent, spreading, an inch in length: petioles shorter by half than the leaves: the peduncles axillary, solitary, filiform, covered with shining bladders, purple, very short: the flowers pendulous, appearing as if frosted with crystalline bladders. It flowers from May to August.

They are all natives of the Cape.

Culture.—The first and fourth sorts may be increased by cuttings, which should be cut off from the plants a few days before they are planted, that the part where they are cut may be healed, setting them out in July, that they may have time to make good roots before winter, on a bed of fresh earth, shading them from the sun in the heat of the day. They should afterwards be frequently refreshed with water in small quantities. In a few weeks, when well rooted, they should be taken up, and planted into pots filled with light fresh undunged earth, and placed in a shady situation until they have taken new root, after which they may be placed with other hardy exotic plants in a sheltered situation, where they may remain till the middle or latter end of October; at which time they should be removed into the green-house, and placed where they may enjoy as much free air as possible in mild weather, as they only require to be protected from the frost, being pretty hardy with respect to cold. As when planted in the full ground in the summer season they are apt to grow rank and large, or even when permitted to root into the ground through the holes at the bottom of the pots, the pots should be frequently removed to prevent it, as they are injured by it.

The first and second sorts are likewise capable of being raised by seeds, sown in a gentle hot-bed or in a warm border of light fresh earth, in

the spring. When the plants are about four inches high, they may be planted out in pots, treating them in the same manner as the cuttings.

And the third sort will grow from cuttings planted early in the spring, in the same manner as the others.

They afford ornament among other potted plants.

TEUCRIUM, a genus furnishing plants of the under-shrubby and herbaceous kinds.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillate*.

The characters are: that the calyx is a one-leaved perianth, half-five-cleft, acute, almost equal, gibbous at the base on one side, permanent: the corolla one-petalled, ringent: tube cylindric, short, ending in an incurved throat: upper lip erect, acute, deeply two-parted beyond the base; the segments at the sides distant: lower lip spreading, tritid: the lateral segments of the same form with the upper lip, almost erect; the middle one very large, and somewhat rounded: the stamens have four awl-shaped filaments, longer than the upper lip of the corolla and ascending in the cleft of it, prominent: anthers small: the pistillum is a four-parted germ: style filiform, situation and size of the stamens: stigmas two, slender: there is no pericarpium: calyx unchanged, fostering the seeds at the bottom: the seeds four, roundish.

The species cultivated are: 1. *T. flavum*, Yellow-flowered Shrubby Germander; 2. *T. Scorodonia*, Sage-leaved Germander, or Wood Sage; 3. *T. Canadense*, Nettle-leaved Germander; 4. *T. montanum*, Dwarf Mountain Germander; 5. *T. Pyrenaicum*, Pyrenean Germander; 6. *T. Polium*, Poley; 7. *T. capitatum*, Round-headed Germander; 8. *T. pumilum*, Dwarf Germander; 9. *T. fruticosum*, Narrow-leaved Tree Germander; 10. *T. latifolium*, Broad-leaved Tree Germander; 11. *T. Creticum*, Cretan Germander; 12. *T. Marum*, Common Marum or Cat-thyme.

The first has a shrubby, branched, pubescent stem, often procumbent at the base: leaves ovate, shining above, pubescent beneath, crenate, obtuse, petioled; the upper ones quite entire; the whorls from two to six-flowered, distinct: the flowers pedicelled. According to Miller, they are of a dirty white colour, and appear in July. It is a native of the South of Europe, &c.

There is a variety, which is hairy, with yellow flowers, with pale white flowers, and with purple flowers.

The second species has a perennial creeping root: the stems a foot and half or two feet high, four-cornered, nearly upright, hairy, leafy, hard,

often purple; panicle racemed: leaves opposite, wrinkled, hairy, veiny, and wrinkled like Sage, somewhat glutinous, strong-smelling, bitter: the flowers are in pairs, on long opposite naked racemes, pedicelled. It is a native of Europe and Morocco, flowering from July to September. It is used sometimes as hops in beer.

The third is a perennial plant, very like the second, but does not creep at the root as that does: the stalks are erect: the leaves are white on their under side, and deeply serrate: the flowers yellow in terminating racemes. It is observed by Marshall, that the plant from Canada has narrower leaves, equally serrate, tomentose beneath, flat: the spike is composed of whorls or scattered flowers, with a very small bracte under each. But the garden plant has larger wrinkled leaves, unequally serrate, scarcely pubescent beneath; and flowers in a subspiked raceme, of six-flowered, six-leaved whorls, with serrate bractes. It is a native of North America, flowering in August and September.

The fourth species, according to Miller, has the root composed of many woody fibres, which spread wide; hence arise several weak, trailing, woody stalks, eight or nine inches long, sending out many branches: the leaves are small, of a deep green: the flowers white, appearing in June and July; but seldom succeeded by seeds in this climate. It is a native of Germany.

There is a variety with much smaller leaves, hoary on their under side.

The fifth has slender shrubby stalks, which trail close upon the ground; they have a purple bark, and are covered with white hairs: the leaves are round at the top, but at their base are contracted in form of a wedge, so as to resemble at first sight the leaves of Ground-ivy, but they are hairy, and of a thicker consistence: the flowers are collected in round bunches at the end of the branches: the corolla is large; and one half of it is purple, the other white. It flowers great part of the summer, but seldom produces seeds in this climate. It grows naturally on the Pyrenean mountains.

The sixth species has the stems suffruticose, round, procumbent: the whole plant tomentose and hoary: the leaves are oblong, lanceolate or almost linear: the flowers sessile, close and lying over each other, small: bractes the length of the calyx: corolla yellow: the middle segment concave, entire. It is a native of the South of Europe, the Levant, &c.

There are several varieties: as Common Yellow Poley, which has the stalks rather herbaceous and trailing, about six inches long and hoary: leaves woolly, about half an inch long, some wedge-shaped; others oblong, ending in obtuse

points, and crenate towards their ends: the flowers collected in oblong thick spikes at the end of the branches, of a deep yellow colour, and appearing at the beginning of June. This grows naturally in Spain.

The Narrow-leaved Yellow Poley, which has woody stalks, erect, branching, and covered with a hoary down, rising six or eight inches high: the leaves linear, woolly, about half an inch long, having sometimes two or three slight indentures on their edges: the flowers collected in roundish spikes at the end of the branches; they are bright yellow, have woolly calyxes, and appear in June and July. It grows naturally in Spain and Portugal.

The White Poley, which has the stems a foot long and trailing: the leaves are a little cottony, entire on the sides, but toothed at the end: the flowers are pretty large, white tinged a little with purple. It is a native of the South of France. There is also the Purple Poley.

The seventh is shrubby, branched at the base: the branches round, tomentose, erect: the leaves sessile, linear-lanceolate, obtuse, often ternate: the flowers corymbed, headed, close: calyxes villose-tomentose: the corolla small, pale yellow or white. It has the habit of *Origanum Majorana*, but is tomentose, and has narrow leaves. It is a native of France, &c.

There is a variety which has an erect branching stalk, which rises a foot high; the lower part becomes woody, but the upper is herbaceous: the leaves are linear-lanceolate, about an inch long, crenate, of a pretty thick consistence, and a little woolly: the flowers collected in a corymb at the end of the branches, white, appearing in July and August.

The eighth species has liginous procumbent slender downy stems, lying on the ground: the leaves in clusters; the flowers reddish, collected into small heads at the ends of the branches; coming out in June and July. It is a native of Spain.

The ninth has a shrubby branching stalk, rising six or eight feet high, and covered with a hoary bark: the leaves opposite, ovate, sessile or on very short petioles, near an inch long, and half an inch broad, smooth and of a shining green above, and hoary beneath: the flowers are axillary from the upper part of the branches, one on each side at a joint, on short peduncles. A native of Spain, &c., flowering in February.

There is a variety which is a little more branched, and has smaller shorter leaves: the flowers are paler, the stamens somewhat longer, the anthers smaller and brown, whereas in the larger sort they are violet: and another with variegated leaves.

The tenth species is a shrubby plant, growing seven or eight feet high, and may be trained to a much greater height: the flowers are somewhat shorter and smaller, though the leaves are larger; they are not blue but purplish, with more conspicuous veins and streaks; the anthers are of a dusky greenish colour; the leaves are broader, of a rhomboid form, more hairy, and whiter on their under side. It is a native of Spain, flowering from June to September.

The eleventh has the leaves acuminate, white beneath: the flowers in threes, or solitary: the calyxes are spiny. It is a native of Candia and Egypt.

The twelfth species has a low shrubby stalk, sending out many slender woody branches, in warm countries rising three or four feet high, but in England rarely half that height: the stalks are very hoary, and have small leaves placed opposite at each joint, about the size of those of Thyme, and pointed at both ends, green above, hoary underneath, having a grateful scent, but so piercing as to cause sneezing: the flowers grow in loose whorled spikes at the ends of the branches; they are very downy, and of a bright red colour; appear in July and August, but produce no seeds in this climate. It is a native of Spain.

Culture.—All the herbaceous and ligneous kinds may be readily increased by parting the roots, by slips of the young branches, and seeds: the roots may be divided in the autumn, or early spring, and the slips of the branches be taken off in the spring and summer, being planted out in moist shady situations; and when well rooted, they may be removed to where they are to remain, though it is best to plant them at once where they are to grow: the seeds may be sown in a bed or border of common earth in the early spring season.

In the *Polium* kinds the seeds should be sown in a bed of light earth, and the plants be either put out in nursery-rows, or set where they are to remain, in the latter end of summer.

The shrubby sorts may likewise be increased by slips or cuttings of the young shoots of the branches, which should be planted in pots filled with light mould, in the spring and summer months, in order to be removed under the protection of the green-house in winter, being afterwards managed as other green-house exotics.

The first sorts afford variety in the borders, &c., and the latter in assemblage with green-house plants.

THALICTRUM, a genus containing plants of the hardy, herbaceous, fibrous-rooted, perennial kinds.

It belongs to the class and order *Polyandria*

Polygynia, and ranks in the natural order of *Multisiliquæ*.

The characters are: that there is no calyx, unless the corolla be taken for it: the corolla has four petals, roundish, obtuse, concave, caducous: the stamina have very many filaments, wider at top, compressed, longer than the corolla: anthers oblong, erect: the pistillum, styles very many, very short: germs many, commonly pedicelled, roundish: styles none: stigmas thickish: there is no pericarpium: the seeds many, grooved, ovate, tailless.

The species cultivated are: 1. *T. tuberosum*, Tuberous-rooted Meadow Rue: 2. *T. Cornuti*, Canadian Meadow Rue: 3. *T. foetidum*, Fetid Meadow Rue: 4. *T. angustifolium*, Narrow-leaved Meadow Rue: 5. *T. lucidum*, Shining-leaved Meadow Rue: 6. *T. aquilegifolium*, Columbine-leaved Meadow Rue, or Feathered Columbine.

The first has knobbed roots: the leaves small, obtuse, indented in three parts at their points, of a grayish colour and smooth: the stalks rise a foot and half high, and are naked almost to the top, where they divide into two or three small ones, under each of which is placed one leaf; every division is terminated by a small bunch of pretty large flowers, disposed almost in form of an umbel, each composed of five white petals. It is a native of Spain, flowering in June.

The second species attains the height of three feet: the stems suffruticose, dark purple, branched: leaves resembling those of Columbine, but glaucous: the flowers in many pale-purple heads, five-petalled and white. It is a native of North America, flowering from May to July.

There is a variety, which is smaller, with pale purple filaments.

The third has the stem about six or seven inches high: the leaves downy, composed of a great number of small leaflets, which are bluntly indented, and have a fetid scent: the flowers in loose panicles, small, and of an herbaceous white colour: the leaves are somewhat hairy on both sides, pulpy and soft: the petals themselves are somewhat hairy, in the young plant reddish, but in the adult whitish, almost a foot high, and not very leafy. It is a native of the South of France, Switzerland, &c., flowering from May to July.

The fourth species has the stems from two to three feet high: the flowers small, collected in terminating panicles, and of an herbaceous white colour. It is a native of Germany and Switzerland, flowering in June and July.

The fifth has the stems upright, channelled, five or six feet high, having at each joint pinnate

THE

leaves, composed of many linear fleshy leaflets, which are for the most part entire, and end in acute points: the flowers are of a yellowish white colour; they appear in July, and are succeeded by small angular capsules, with one small oblong seed in each, which ripens in August. It is a native of France about Paris, and of Spain.

The sixth species has a thick fibrous root; the stems taper, rising three feet high: the leaves like those of Columbine: the flowers in large terminating panicles. It is a native of Scania, Switzerland, &c.

There are varieties with a green stalk and white stamens, and with a purple stalk and stamens. There are other sorts that may be cultivated for variety.

Culture.—All the sorts are readily increased by parting the roots, and planting them out in the autumn when the stems decay, or in the spring before the new ones are sent forth, in the strongest where they are to remain, and the weaker ones in nursery-rows for further growth: they may also be raised from seeds, which should be sown in a bed or border in the spring; when the plants rise, they should be kept clean, and be planted out where they are to remain, in the following autumn. They afford variety in the borders, and other parts of ornamented grounds.

THEA, a genus furnishing plants of the exotic shrubby kind.

It belongs to the class and order *Polyandria Monogynia*, (*Trigynia*), and ranks in the natural order of *Columniferae*.

The characters are: that the perianth is five-parted, very small, flat, inferior, permanent: segments roundish, obtuse, equal: the corolla has six petals, (three to nine) roundish, concave, large; of which two are exterior and a little smaller: the stamens have numerous filaments, (more than two hundred) filiform, shorter than the corolla, inserted into the receptacle: anthers cordate, fastened by the back: the pistillum is a globular-trigonal germ: styles three, united at the base, at bottom erect, closely approximating, and as it were united into one; above the stamens diverging, somewhat recurved at the top, after flowering separated to the very base, reflexed at the top: stigmas simple: the pericarpium is a trilocular capsule, trifolocular, gaping at the top, in three directions: the seeds solitary, globose, angular on the inward side.

The species is *Thea*, Tea-Tree.

It is commonly about the height of a man. It is described indeed by different authors, as varying much in size, from that just mentioned to thirty and even two hundred feet. Probably it may attain the height of thirty feet or more

THE

when left to itself; but in general the trees are cut down periodically, that they may make stronger shoots, and therefore are seldom seen to be above five or six feet high. The trunk is branching and round: the branches alternate or vague, suffish, inclining to an ash-colour, but reddish towards the end: the leaves alternate, elliptic, smooth, glossy, of a firm texture, bluntly serrate except near the base, blunt and for the most part slightly emarginate at the end, veined on the under side, on very short petioles, round and gibbous beneath, flatish and slightly channelled above: the stipules to the leaves none: peduncles axillary, alternate, single, curved, one-flowered, incrassate, having at the base a single stipule or bracte, which is awl-shaped, erect, elliptic, obtusely serrate, with the edges between the teeth recurved: the corolla white, varying in the number and size of the petals: the stamens, according to Loureiro, inserted rather into the base of the corolla than into the receptacle.

In respect to the varieties, Martyn has considered them all as forming one species, in which, he is, he says, supported by the best authorities. "Kämpfer," says he, "attributes their difference to soil, culture, age of the leaves, and method of curing them. Mr. Ellis directly asserts that the Green and Bohea Tea are one and the same species; and that it is the nature of the soil, the culture, and manner of gathering and drying the leaves, that makes the difference; and a Green Tea-tree planted in the Bohea country will produce Bohea Tea, and the contrary. So also Sir George Staunton says; every information received concerning the Tea plant concurred in affirming, that its qualities depended upon the soil in which it grew, and the age at which the leaves were plucked off the tree, as well as upon the management of them afterwards. Linnæus, it is well known, distinguished two species of *Thea*; the *Bohea* with six-petalled flowers, and the *Viridis* or Green with nine-petalled flowers: but it is now well ascertained that the number of petals is very uncertain; and Dr. Lettsom informs us that he has examined several hundred flowers both from the Bohea and Green countries, and that their botanical characters have always appeared uniform. In the catalogue of the royal botanic garden at Kew, two varieties of *Thea Bohea* are given, distinguished by the leaves; namely, *Laxa* or Broad-leaved Tea, with elliptic-oblong wrinkled leaves; and *Stricta*, or Narrow-leaved Tea, with lanceolate flat leaves. The Bohea Tea-trees now introduced into many botanic gardens near London, exhibit very obvious varieties: the leaves are of a deeper green colour, and not so deeply serrated; and the stalk is usually of a darker colour: but the botanical characters

are the same. Thunberg also distinguishes two varieties from the leaves, which in one are smaller, flat, darker green, with straight serratures, and in the other larger, waved, brighter green, with sinuate serratures: but they can scarcely be considered as distinct species. Loureiro observed little difference in the Sou-chong, which he examined: both these have a brown colour, but are more odoriferous and precious than the common Bohea of the province of Fo-kien, which he had not an opportunity of seeing in a living state, though it is the most common and cheapest of all. He examined the dry flowers of the Green tea, from the province of Kiang-si, and observed the same inconstancy, as to the number of parts in the calyx and corolla, as in the Bohea. Upon the whole he concludes that all the differences of Chinese tea form only one botanical species, owing their variation to soil, culture, and method of preparation; all retaining the same inconstancy in the parts of the flower, which gave occasion to Linnæus to consider them as two species."

It is added, "that many varieties of tea are known in China, from mixture and management." The distinctions chiefly regarded in Europe are the following.

"*Green Teas.*—1. Bing, Imperial or Bloom Tea, with a large loose leaf, of a light green colour, and a faint delicate smell.

"2. Hy-tiann, Hikiong, Hayssuen or Heechun, known to us by the name of Hyson Tea: the leaves are closely curled and small, of a green colour verging towards blue. Another Hyson Tea, with narrow short leaves, is called Hyson-utchin. There is also a green tea named Gôbû, with long narrow leaves.

"3. Song-lo or Singlo, which name it receives, like several others, from the place where it is cultivated."

"*Bohea Teas.*—1. Soo-chuen, Sut-chong, Sou-chong, or Su-chong, called by the Chinese Saa-tyang, and Sact-chaon or Sy-tyann, is a superior kind of Cong-fou Tea. It imparts a yellowish green colour by infusion, and has its name from a place or province in China. Padre Sutchong has a finer taste and smell: the leaves are large and yellowish, not rolled up, and packed in papers of half a pound each. It is generally conveyed by caravans into Russia; without much care it will be injured at sea. It is rarely to be met with in England.

"2. Cam-bo or Soum-lo, called after the name of the place where it is gathered: a fragrant tea with a violet smell; its infusion is pale.

"3. Cong-fou, Congo, or Bong-lo: this has a larger leaf than the following, and the infusion is a little deeper coloured. It resembles the common Bohea in the colour of the leaf.

"There is a sort called Lin-Kisam, with narrow rough leaves. It is seldom used alone, but mixed with other kinds. By adding it to Congo, the Chinese sometimes make a kind of Pekoe tea.

"4. Pekao, Pecko, or Pekoe, by the Chinese called Back-ho or Pack-ho. It is known by having the appearance of small white flowers intermixed with it.

"5. Common Bohea or Black Tea, called Moji or Mo-ee by the Chinese, consists of leaves of one colour. The best is named Tao-kyonn. An inferior kind is called Au-kai, from a place of that name. In the district of Honan, near Canton, the tea is very coarse, the leaves yellow or brownish, and the taste the least agreeable of any. By the Chinese it is named Honan-té, or Kuli-té.

"Besides these, Tea both Bohea and Green is sometimes imported in balls, from two ounces to the size of a nutmeg and of peas. The Chinese call it Poncul-tcha. The smallest in this form is well known under the name of Gunpowder Tea.

"Sometimes the succulent leaves are twisted like packthread, an inch and half or two inches long; three of these are usually tied together at the ends by different-coloured silk threads. Both Green and Bohea are prepared in this manner.

"The manner of gathering and preparing the leaves, as practised in Japan," according to Kämpfer, "as far as our information reaches, is in a great measure conformable to the method used by the Chinese.

"The leaves are gathered carefully one by one, and each person is able thus to collect from four to ten or fifteen pounds in one day. The first gathering commences about the end of our February, or beginning of March, when the leaves are young and tender: they are called Ficki Tsjaa or powdered tea, because they are pulverised and sipped in hot water: they are disposed of to princes and rich people only, and hence this kind is called Imperial Tea.

"A similar sort is called Udsi Tsjaa, and Tacke Sacki Tsjaa, from the places where it grows. Peculiar care and nicety is observed in gathering these leaves.

"The second collection is made at the end of March or beginning of April. This is called Toot-jaa, or Chinese Tea, because it is infused and drunk after the Chinese manner.

"The third gathering is made in June, when the leaves are full grown. This is called Bau Tsjaa; it is the coarsest, and is chiefly consumed by the lower class of people. By sorting these, several other varieties are produced.

"Whether the Chinese collect the tea precisely at the same seasons as in Japan, we are not well informed; but most probably the tea

harvest is nearly at the same periods, the natives having frequent intercourse, and their commercial concerns with each other being very extensive.

"The tea leaves should be dried as soon as possible after they are gathered. For this purpose public buildings are erected, containing from five to ten, and even twenty small furnaces about three feet high, each having at the top a large iron pan. There is also a long table covered with mats, on which the leaves are laid, and rolled by workmen who sit round it. The iron pan being heated to a certain degree by a fire made in the furnace beneath, a few pounds of the leaves are put upon the pan, and continually turned and shifted by the hands till they become too hot to be endured; they are then thrown upon the mats to be rolled between the palms of the hands; after which, they are cooled as speedily as possible. In order that all the moisture of the leaves may be completely dissipated, and their twisted form be better preserved, the above process is repeated several times with the same leaves, but less heat is employed than at first. The tea thus manufactured is afterwards sorted according to its kind or goodness. Some of the young tender leaves are never rolled, and are immersed in hot water before they are dried.

"Country people cure their leaves in earthen kettles, which answer every necessary purpose, at less trouble and expense, whereby they are enabled to sell them cheaper.

"After the tea has been kept for some months, it is taken out of the vessels in which it was stored, and dried again over a very gentle fire, that it may be deprived of any humidity which remained, or it might have since contracted.

"The common tea is kept in earthen pots with narrow mouths; but the best sort used by the emperor and nobility is put into porcelain or china vessels. The coarsest tea is kept by the country people in straw baskets, made in the shape of barrels, which they place under the roofs of their houses, near the hole that lets out the smoke."

Culture.—These plants may be raised in this country by seeds, layers and cuttings of the young branches. The editor of Miller's Dictionary advises that the seeds should be procured from China, and that care should "be taken that they be fresh, sound, ripe, white, plump, and moist internally. After being well dried in the sun, they may be inclosed in bees-wax, or, left in their capsules, they may be put into very close canisters of tin or tutenague. Thouin, in his directions to Proust, he says, recommends

VOL. II.

these and other seeds to be placed in alternate layers of earth or sand, in tin boxes, closed up exactly, and placed in solid cases, covered with waxed cloth; the boxes to be placed in a part of the ship the least accessible to moisture, and the most sheltered from extreme heat or cold." And "Mr. Sneyd," he adds, "was very successful in having seeds packed up in absorbent paper, and surrounded by raisins or moist sugar, which kept them in a state fit for vegetation. American seeds are frequently brought over, by putting them into a box, not made too close, upon alternate layers of moss, in such a manner as to admit the seeds to vegetate. This might be tried with the seeds of the Tea-tree; and to succeed more certainly, some of the seeds might be sown in pots or boxes, when the vessel arrives at St. Helena, and after passing the tropic of Cancer, near the latitude of thirty degrees north. But the best method" says he, "seems to be, to sow ripe seeds in good light earth in boxes, at leaving Canton; covering them with wire, to prevent rats and other vermin from coming to them; and taking care that the boxes be not exposed to too much air, nor to the spray of the sea. A little fresh or rain water should be sprinkled over them now and then; and when the seedling plants appear, they should be kept moist, and out of the burning sun. If young plants can be procured in China, they may be sent over in a growing state in boxes, forty inches long by twenty broad, and as much in depth, having a few holes bored through the bottom. When the trees arrive here they must be kept in a green-house during the winter, and in the open air during the summer; and if they come in bad condition, it may not be amiss to plunge the pots into which they are transplanted, in a gentle hot-bed, or to set them in the tan-pit, to make them strike and shoot more freely." It is further remarked, that "though the Tea-tree will not at present bear the rigour of our winters, in the open air, yet it is not impossible but it may gradually become naturalized to our climate, like the Magnolia, among several other trees and shrubs; especially if it were to be brought from the coldest provinces of China, where it grows, or from the parts of Europe a little to the southward of us, when it shall have been naturalized there." It is increased freely from cuttings, when managed in the same manner as Gardenias; and it also sometimes grows from layers laid down in the autumn or spring.

Some of these plants should be always kept in pots, to be removed under the shelter either of a green-house, glass case, or deep garden frame, in winter; and others be planted in a dry, well-

sheltered, warm, conspicuous part of the shrubbery, to afford occasional covering from rigorous frosts.

They afford variety in green-house collections, as well as in the shrubberies.

THEOBROMA, a genus containing a plant of the exotic tree kind.

It belongs to the class and order *Polyadelphia Decandria*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a five-leaved perianth: leaflets lanceolate, acute, spreading, deciduous: the corolla has five petals, smaller than the calyx: claws wide, arched, concave like a helmet, emarginate at the tip, scored internally with a thick triple line inserted into the nectary at the base: borders roundish, acuminate, spreading, each narrowed at the base into a small claw which is from upright recurved, and fastened into the claw: nectary a short little pitcher, putting forth five little horns, which are awl-shaped, long, erect, acuminate, bent in and converging, decurrent along the pitcher: the stamina have five filiform filaments, erect, bent outwards at top, lying within the claws of the petals, growing externally to the nectary, alternate with and shorter than the horns: anthers on each filament two, (one on each side at the tip,) vertical, one cell superior, the other inferior: the pistillum is an ovate germ: style filiform, (striated, Aubl.) a little longer than the stamens: stigma five-cleft: the pericarpium is an oblong capsule, coriaceous, unequal, five-cornered, five-celled, valveless, not opening: the seeds very many, subovate, nestling in a buttery pulp, fastened to a central columnar receptacle.

The species is *T. Cacao*, Chocolate Nut Tree.

It grows in a very handsome form to the height of twelve or sixteen feet: the trunk is upright, and about as high as a man before the head spreads out: the wood is light and of a white colour, and the bark is brownish and even: the leaves lanceolate-oblong, bright green, quite entire, alternate, from nine to sixteen inches long, and three or four inches wide at most, on a petiole an inch in length and thickened at both ends: the peduncles slender, about eight or ten together, chiefly from the scars of the fallen leaves: one of them only for the most part fruitful, the rest abortive: the flowers small, reddish, inodorous: fruit smooth, yellow, red, or of both colours, about three inches in diameter: rind fleshy, near half an inch in thickness, flesh-coloured within: pulp whitish, the consistence of butter, separating from the rind in a state of ripeness, and adhering to it

only by filaments, which penetrate it and reach to the seeds. Hence it is known when the seeds are ripe, by the rattling of the capsule when it is shaken: the pulp has a sweet and not unpleasant taste, with a slight acidity; it is sucked and eaten raw by the natives: it may be easily separated into as many parts as there are seeds, to which it adheres strongly, and they are wrapped up in it, so that each seed seems to have its own proper pulp: the seeds are about twenty-five in number: when fresh they are of a flesh-colour: gathered before they are ripe, they preserve them in sugar, and thus they are very grateful to the palate: they quickly lose their power of vegetation, if taken out of the capsule, but kept in it they preserve that power for a long time: the tree bears leaves, flowers, and fruit all the year through; but the usual seasons for gathering the fruit are June and December: in two years from the seed it is above three feet high, and spreads its branches, not more than five of which are suffered to remain: before its third year is complete it shows for fruit: a tree yields from two to three pounds of seeds annually. It is a native of South America.

Culture.—It is increased by seed obtained from abroad, sowing it as soon after its arrival as possible, in pots filled with light earth, and plunging them in a bark-bed, where they will soon come up; and when the plants are about three inches high, potting them off separately, and replunging them in the bark-bed in the stove, managing them as other woody exotics of the stove kind afterwards.

They afford an agreeable variety in stove collections.

THERMOMETER, an instrument constructed for the purpose of measuring the degrees of heat and cold at all seasons, and which is of great utility in the culture of tender exotic stove plants, by serving as a guide to regulate the proper degree of heat for the hot-houses containing such plants.

Their construction for this use consists of a long slender glass tube, or pipe, about eighteen inches or two feet long, having a small glass ball or globe at the lower end; and it is fixed longitudinally on a brass or wooden plate or frame, the same length, or longer, and four or five inches broad; the glass tube and ball being furnished with a quantity of coloured liquid spirit, or other fluid, which is affected by heat and cold so as to ascend higher or lower in the tube proportionably, a scale being marked on the frame along each side of the tube, divided into the different degrees of heat and cold: and the spirit ascending by the heat of the internal

air of the stove, promoted by fire, &c. points out on the scale the proper degree of heat required, having the name of some remarkable exotic, such as the ananas, or pine-apple, written on the scale as a standard mark of the requisite temperature of heat, so as when the internal heat of the stove raises the spirit to that mark, or within five degrees over or under, is the proper temperature for the growth of the ananas, and all other tender plants from the hottest parts of the world; so that the fires requisite for the stove in winter, are to be made stronger or weaker accordingly.

They are more particularly useful in winter, during the time the fires are made in the flues for warming the air internally; one being generally hung up toward the centre of the stove, so as the warmth may operate moderately and equally on every side, and discover the real temperature of the general internal heat, which should be supported always nearly equal by the aid of bark hot-heus and real fire, sufficient to raise the spirit or other fluid in the tube to the mark ananas, or but a little over or under it.

They should not only be suspended nearly towards the centre of the stove, but also out of the sun, that the glass tube and ball containing the spirit or other fluid may be shaded as much as possible; and also at some medium distance from the fire-place and flues, so as neither the direct rays of the sun, or heat of the fire, darting immediately on the tube and ball, may affect the operation of the inclosed fluid, and cause it to mount higher than would be effected by the real general warmth of the air of the stove, and thereby lead into an error, in supposing the internal heat to be much stronger than it really is, when probably it is not strong enough. See ANANAS.

THICKETS, a sort of close plantations of trees and shrubs, in pleasure-grounds, parks, &c. They are designed for different purposes, as sometimes to repel the force of tempestuous and cold cutting winds, either from the habitation, or some particular part of the garden; or to form places of shade or retirement in summer, having spaces for walks, recesses, &c. under the umbrage of the trees, and occasionally to conceal from view any unsightly or disagreeable object, and also sometimes to form a screen or blind arranged towards some outward boundary.

On some occasions, they are introduced in the internal parts of large pleasure-grounds, and parks, in contrast to the more open and airy plantations, in which to have shady wood-walks winding variously through them, also to form recesses, by environing particular spaces,

rendering them retired, shady, and sheltered, by the surrounding trees and shrubs composing the thickets: close thickets of hardy trees and shrubs are sometimes also disposed in detached clumps in capacious open situations, to effect a diversified ornamental variety, the clumps being distantly stationed so as not to obstruct the view of any desirable object.

They are sometimes planted wholly of the large tree kinds, five or six to eight or ten feet asunder, some in regular lines like a close grove, or more generally in a sort of promiscuous planting, but with some degree of order in the distances: they are also often composed of various trees and shrubs together to effect a more full, close growth below and above, and to display a greater diversity in the plantation, by disposing the various shrubs properly between the larger trees, in some order of gradation, the lowest towards the front, and the taller growths backward, so as to form a sort of close underwood thicket below, while the trees run up and form a thickety growth above: and sometimes they are formed wholly of shrubs of different sorts and degrees of growth, from the lowest placed forward to the tallest behind.

They are sometimes formed wholly of particular sorts of trees disposed separately in distinct plantations, as of elm, ash, beech, poplar, alder, willow, &c.

The planting of thicket plantations should be effected with young trees of from four, five or six, to eight or ten feet growth, and the shrub kinds proportionally; in all of which the planting may be performed in the common seasons of autumn, winter and spring.

In the culture of thicket plantations, little is required but that of keeping them clear from large overbearing weeds, while the trees and shrubs are in young small growth.

THOROW-WAX. See **BOPLEURUM.**

THUJA, a genus containing a plant of the hardy evergreen tree kind.

It belongs to the class and order *Monœcia Monadelphica*, and ranks in the natural order of *Coniferæ*.

The characters are: that in the male flower the calyx is an ovate ament, composed of a common rachis, on which opposite flowers are placed in a triple opposition: each flower has for its base a subovate, concave, obtuse scale: there is no corolla: the stamina have four filaments (in each floret) scarcely manifest: anthers as many, fastened to the base of the calycine scale:—female flower on the same plant: the calyx is a common subovate strobile, surrounded with opposite florets; composed of two-flowered, ovate, convex scales, converging longitudinally: there is no corolla: the pistillum is a very small germ: style awl-shaped: stigma simple: the pericarpium is an ovate-oblong strobile, obtuse, opening longitudinally, with oblong scales, almost equal, convex outwardly, obtuse: the seeds oblong, girt longitudinally with a membranaceous wing, emarginate.

The species cultivated are: 1. *T. occidentalis*, American Arbor-vitæ; 2. *T. orientalis*, Chinese Arbor-vitæ.

The first has a strong woody trunk, which rises to the height of forty feet or more: the bark, while young, is smooth and of a dark brown colour, but as the trees advance the bark becomes cracked, and less smooth: the branches are produced irregularly on every side, standing almost horizontal, and the young slender shoots frequently hang down: these branches stand but thin, and the younger branches only have leaves, so that when the trees are grown large they make but an indifferent appearance, being so thinly clothed with the leaves: the young branches are flat, and the small leaves are placed over each other like the scales of fish: the flowers are produced from the side of the young branches, pretty near to the footstalk: the males grow in oblong catkins, and between these the females are collected in form of cones. When the former have shed their farina, they soon drop off; but the latter are succeeded by oblong cones, or strobiles, having obtuse smooth scales, containing one or two oblong seeds. It is a native of Siberia and Canada, where it is very plentiful, but not much further south.

There are different varieties; as the American Sweet-scented, and Variegated-leaved.

The second species has the branches growing closer together, and much more adorned with leaves, which are of a brighter green colour, and

make a much better appearance than the former: the branches cross each other at right angles: the leaves are flat, but the single divisions are slender, and the scales smaller, and lie closer over each other than those of the first sort: the cones (strobiles) are also much larger, of a beautiful gray colour, and their scales end in acute reflexed points. It is a native of China and Japan.

Culture.—These plants may be increased by seeds, layers, and cuttings.

Good seeds should be obtained and be sown soon after they are ripe, or as soon as they can be obtained, in autumn or spring, in pots or boxes of light earth, covering them half an inch deep, placing the pots, &c. in a sheltered warm situation, or under the shelter of a frame in bad weather, especially when sown in autumn, that they may be protected from severe frosts: they sometimes come up in the spring, but are frequently apt to remain in the ground till the second year. When the plants are come up, the pots should be placed in an east border to have only the morning sun, but open to the free air, giving frequent but very moderate waterings all the summer; and in winter removing the pots again to a sheltered place till spring, when they may be pricked out in nursery-rows; or, when they are small and weakly, continued in the pots another year, placing them in a shady situation during summer, and in a sheltered place in winter; and in spring following planting them out in the nursery, in rows a foot or two asunder, to remain to acquire size and strength for planting out where they are to remain.

The layers should be made from the young shoots of one or two years growth, which may be laid down early in autumn, bending down the branches to the earth, and laying all the young wood in by slit- or twist-laying, with the tops only appearing a little above ground; shortening any that have much longer tops than the others: they mostly emit roots in the earth, and form proper plants by autumn following; when, or rather in spring after, they should be separated from the stools, and be planted in nursery-rows, to remain two or three years, or till of a proper size for the shrubbery, &c.

The cuttings should be made from the strong young shoots of the same year's growth, which should be planted in the autumn, in a shady border, taking the opportunity of showery weather, if possible, for the business: they should be cut off with a small part of the old wood, where practicable, and be planted in rows a foot asunder, closing the earth well about them: they will be properly rooted in one year

for planting out in wider nursery-rows: they may also be planted in pots, and placed in a hot-bed, in order to have them more forward.

They may be planted out into the borders, &c. in the autumn or early spring months.

They are highly ornamental evergreens, proper for adorning the shrubbery and other parts, having a fine effect also when disposed singly in borders, &c. and in open spaces of grass; in all of which situations they should be suffered to grow with their full branches, in their own natural way, except reducing with a knife any low straggling or rambling branches occasionally: this is all the culture they require afterwards.

They may also be employed as timber-trees, in the evergreen forest-tree plantations.

And those in the pots, as the Chinese Arbor Vitæ, may be placed among other potted plants to adorn any particular compartment, and in assemblage with green-house plants for variety.

THUYA. See THUJA.

THYMBRA, a genus furnishing plants of the under shrubby, exotic kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatæ* or *Labiatæ*.

The characters are: that the calyx is a one-leaved perianth, subcylindrical, keeled at the sides, two-lipped at the mouth: upper lip wider, half-three-cleft, equal, converging; lower narrower, two-parted: the corolla is ringent: tube subcylindrical: upper lip flat, straight, half-two-cleft, obtuse; lower three-cleft, almost equal, flat: the stamina have four filiform filaments, approaching by pairs: the two lower ones shorter: anthers two-lobed: lobes remote, under the upper lip of the corolla: the pistillum is a four-cleft germ: style filiform, half-two-cleft: stigmas two, acute: there is no pericarpium: calyx unchanged: the seeds four.

The species cultivated are: 1. *T. spicata*, Spiked Thymbra; 2. *T. verticillata*, Whorled Thymbra.

The first is a low shrubby plant like heath, branching out into slender woody stalks which are six or eight inches long, covered with a brown bark, and garnished with narrow acute-pointed leaves about half an inch long, sitting close to the stalks opposite; they have an aromatic odour when bruised: the stalks are terminated by thick close spikes of purple flowers, near two inches long: the calyxes are stiff and hairy; they are cut half their length into acute segments: out of these the flowers peep, with their two lips; the upper is concave and arched, the under cut into three equal portions, and these are a little reflexed: they appear in June

and July, and in warm seasons are sometimes succeeded by seeds which ripen in autumn. It is a native of Mount Libanus, Macedonia, Spain, &c.

The second species has a shrubby stalk which seldom rises much more than a foot high, putting out many small woody branches, which have narrow spear-shaped leaves with many punctures; they stand opposite, and are of an aromatic flavour: the flowers grow in whorled spikes at the end of the branches: the leaves which stand under each whorl are broader than those below, and are covered with fine hairs: the flowers are purple, and sit close to the stalks: the upper lip is concave, and ends with two obtuse points; the lower ends with three equal points: these appear about the same time with the other, and in warm seasons the seeds ripen in this climate. It is a native of Spain and Italy.

Culture.—These plants may be increased by seeds, slips, and cuttings.

The seeds should be sown in the early spring in a warm border, and sheltered from bad weather by glasses; or, which is better, in pots filled with light mould, and placed in a mild hot-bed: when the plants have attained some growth they should be set out or removed into separate pots.

The slips and cuttings should be planted out in the spring and summer, and when well rooted removed where they are to grow: they also sometimes succeed by bottom offsets planted out as above.

They afford variety among other potted green-house plants.

THYME. See THYMUS.

THYMUS, a genus containing plants of the low, aromatic, perennial kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatæ* or *Labiatæ*.

The characters are: that the calyx is a one-leaved perianth, tubular, half-five-cleft into two lips, permanent, having the throat closed with villose hairs: upper lip wider, flat, erect, three-toothed: lower lip two-bristled, of equal length: the corolla one-petalled, ringent: tube length of the calyx: throat small: upper lip shorter, flat, erect, emarginate, obtuse; lower lip longer, spreading, wider, triid, obtuse: middle segment wider: the stamina have four filaments, curved in, two of which are longer: anthers small: the pistillum is a four-parted germ: style filiform: stigma bifid, acute: there is no pericarpium: calyx narrowed at the neck, cherishing the seeds in its bosom: the seeds four, small, roundish.

The species cultivated are: 1. *T. Serpillum*,

Wild Thyme; 2. *T. vulgaris*, Garden Thyme; 3. *T. Mastichina*, Mastic Thyme; 4. *T. Virginicus*, Virginian or Savory Thyme.

The first has a woody, fibrous, brown, perennial root: the stems numerous, woody, branched, leafy, pubescent, commonly tinged with red: branches alternate: the leaves petioled, elliptic or ovate, obtuse, quite entire, hollow-dotted with little pellucid glands, ciliate at the base and on the petiole with a few fine white hairs; otherwise it is commonly smooth, though sometimes hairy all over: the heads of flowers terminating, roundish, with little leaves among them: the flowers pedicelled, and of a purplish red colour. It is a native of Europe, flowering in July and August.

There are several varieties; as the Broad-leaved, Narrow-leaved, Variegated-leaved, Silver-striped-leaved, Citron-scented or Lemon Thyme, Great Purple-flowered.

The second species is more hoary, higher, harder, and more woody than the first: the leaves are whiter, narrower, and the flowers smaller. It is a native of the South of Europe and Siberia, flowering from May to August.

There are different varieties; as the Broad-leaved, the Narrow-leaved, and the Variegated or Striped-leaved Thyme.

The third is a shrub, a foot in height, or a little more: the leaves heaped on the stem, linear or even ovate, the lower hoary beneath, the upper ones smooth: whorls hirsute: the teeth of the calyx hairy, and as it were feathered. It is a native of Spain.

The fourth species has a perennial root; but the stalk is annual, rising about a foot and half high, stiff, angular, branching out towards the top: the leaves stiff, pointed, about an inch and half long, and a quarter of an inch broad in the middle, pointed at both ends, and having a strong scent of pennyroyal: the flowers are white, collected into globular heads, appearing in July; but the seeds seldom ripen in this climate. It is a native of North America.

Culture.—These plants may be easily raised from seed, by slipping the roots and branches, and by cuttings; but the seed method is seldom practised except with the second sort, or Garden Thyme: the seed should be sown in the early spring on light, rich, dry ground, which should be properly dug over, and the surface be made moderately smooth with the spade: as the seed is small, it should not be sown too thick, or be covered too deep: the seed is best sown while the ground is fresh stirred, either broad-cast on the surface, raking it in lightly, or in flat shallow drills, earthed over thinly: the plants appear

in two or three weeks. It is necessary to be careful to keep them well weeded, giving occasional light waterings in dry weather; and by June they will require thinning, especially if the plants are to grow stocky, and with bushy full heads; in which case they should be set out to six or eight inches distance; when those thinned out may be planted in another place, in rows, six or eight inches asunder, giving water till fresh rooted, keeping the whole clean from weeds by occasional hoeing between them in dry days, which will also stir the surface of the earth, and much improve the growth of the plants: they will be in perfection for use in summer or early in autumn.

Sometimes the market kitchen-gardeners raise large quantities in beds, for daily supply, leaving the whole thick: when of proper growth they pull them clean up root and top together, from time to time, as wanted, and tie them in bunches for sale.

But it is always proper to thin out, or transplant a quantity in single bunches, to grow stocky and bushy for occasional supplies.

When intended to increase any particular varieties, and continue them the same with certainty, it can only be effected by slips and cuttings.

In respect to the offsets and slips, all the sorts multiply by offsets of the root and slips of the branches: the rooted slips are the most expeditious method, as the old plants increase into many offset-stems rising from the root, each furnished with fibres; and by taking up the old plants in the spring, &c. and slipping or dividing them into separate parts, not too small, with roots to each, and planting them in beds of good earth, in rows half a foot asunder, giving water directly, and repeating it occasionally in dry weather till they have taken root, and begin to shoot at top; they soon grow freely, and form good bushy plants in two or three months.

The strong slips of the branches without roots, succeed when planted any time in the early spring season in a shady border, in rows four or five inches distant, giving due waterings; and become good plants by autumn, when they may be planted out where they are to remain.

The cuttings of the young branches grow readily, the same as the slips, when planted at the same season in a shady place, and well watered.

The Common Thyme is in universal use as a pot-herb for various culinary purposes; it may also be employed in assemblage with other small plants, to embellish the fronts of flower-borders, shrubby clumps, small and sloping banks, &c. placing the plants detached or singly,

to form little bushy tufts, and in which the variegated sorts, and the Silver Thyme and Lemon Thyme particularly, form a very agreeable variety. The Lemon Thyme is also in much estimation for its peculiar odoriferous smell. Some of each of these sorts may also be potted, in order to move occasionally to any particular places as may be required, and under occasional shelter in severe winters to preserve the plants more effectually in a lively state; likewise some of the Mastic Thyme. Spanish and Portugal Thymes are also sometimes potted for the same purpose, and to place under the protection of a garden frame or green-house in winter, to continue them in a more fresh and lively growth: and sometimes some of the smaller Thymes are sown or planted for edgings to particular beds or borders for variety, such as the Lemon Thyme, Silver-leaved and variegated sorts; also occasionally the Common Thyme; and all kept low, close, and regular, by clipping them at the sides and tops annually in the summer season.

TICKSEED-SUN-FLOWER. See **COREOPSIS**.

TILIA, a genus containing plants of the ornamental tree kind.

It belongs to the class and order *Polyandria Monogynia*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a five-parted perianth, concave, coloured, almost the size of the corolla, deciduous: the corolla has five petals, oblong, obtuse, crenate at the tip: the stamens have numerous filaments, (thirty and more) awl-shaped, length of the corolla: anthers simple: the pistillum is a roundish germ: style filiform, length of the stamens: stigma a blunt pentagon: the pericarpium is a coriaceous capsule, globular, five-celled, five-valved, opening at the base: the seeds solitary, roundish.

The species are: 1. *T. Europæa*, European Lime Tree; 2. *T. Americana*, Broad-leaved American Lime Tree; 3. *T. pubescens*, Pubescent Carolina Lime Tree; 4. *T. alba*, White Lime Tree.

The first is a tall upright tree, with smooth spreading branches thickly clothed with alternate, petioled, heart-shaped, smooth, serrate leaves, pointed at the end, oblique at the base, glaucous beneath, and the veins, where they branch off from the nerve, being furnished with a tuft of glandular wool, as in the *Laurustinus*: the flowers, which are delightfully fragrant, especially at night, come forth in July, in umbels or cymes, (from three to five together,) on long axillary peduncles, with a singular, oblong, blunt, membranaceous, pale, entire bracte, nearly

as long as the peduncle, and attached to it for about half its length, and falling off with it. It is a native of Europe, &c.

It is, though little used, a handsome tree, having a smooth taper straight trunk, and the branches forming a beautiful cone. The foliage also is smooth and elegant: it grows to a very large size, and affords good shade: it makes a fine detached object in parks and open lawns, planted singly: the branches are so tough as seldom to be broken by the winds, and the flowers have a delightful fragrance: the wood is soft, but capable of being turned into light bowls and dishes, &c.

There are several varieties; as the Narrow-leaved, the Broad-leaved, the Elm-leaved, the Red-twiggèd, the Smooth Small-leaved, the Smooth Large-leaved, the Soft Hairy-leaved, the Wrinkled-leaved, and the Striped-leaved.

The second species has the branches covered with a dark brown bark: the leaves are large, heart-shaped, ending in acute points, are deeply serrate, and of a full green on their upper side, but of a pale green and a little hairy on their under side, standing upon long slender footstalks: the petals are narrower, and have nectariums growing to their base: the flowers do not appear till late in July, a full month after the common sort. It is a native of Virginia and Canada, and was brought from New England by the name of Black Lime.

The third is a tree of much smaller growth than either of the former: the branches spread more horizontally: the leaves are smaller, and have a smoother surface; they are heart-shaped, but the midrib runs obliquely to the footstalk, so that one side of the leaf is much larger than the other; the edges are slightly serrate, and their ends run out into long acute points: the bunches of flowers stand upon long slender footstalks; the petals are narrow, and end in acute points; have each a narrow, nectarium fastened to their base on the inside, standing erect close to the petals: the flowers emit a very fragrant odour, and come out towards the end of July. It is a native of Carolina.

The fourth species has the leaves snow-white beneath, and the flowers as in the second sort, but smaller. It is a native of North America, or Hungary.

Culture.—These trees may be increased by seeds, layers and cuttings.

The seed, when ripe in the autumn, should be beaten down, keeping the green-twiggèd and red-twiggèd sorts separate; and be sown soon after, or preserved dry and sound till spring; sowing it in a bed or border of common earth, previously digging the ground, and dividing it

into four-foot wide beds; drawing the earth off the surface evenly, about an inch deep, into the alleys; then sowing the seeds thinly, touching them lightly down into the earth with the back of the spade, directly earthing them over to the above depth.

When they come up in the spring, the beds should be kept clean from weeds, giving moderate waterings in dry weather, to forward the plants in growth as much as possible, in order to be fit for planting out in nursery-rows by autumn or spring following; though, if they have shot rather weakly, they should stand another year, then be planted out in rows two feet and a-half asunder, by eighteen inches distance in the lines, to remain three or four years or more to acquire a proper size for the purposes intended, trimming off the large side-branches from the lower part of the stem occasionally, to encourage their aspiring more expeditiously at top, which should be suffered to remain entire: these trees, when raised from seed, generally assume a more handsome and expeditious growth than such as are raised from layers and cuttings. When they are from about five or six to eight or ten feet high, they are of proper size for final planting out; though, when designed as forest-trees for timber, it is advisable to plant them finally while they are young, as not more than from three or four to five or six feet high.

They are all raised readily by the layer method; and for this purpose proper stools must be prepared, and the young shoots of a year or two old are the proper parts for being laid down, which should be performed in autumn or winter, by slit-laying, shortening the tops of each layer within a little of the ground: they are mostly rooted by autumn following, and fit to plant out in nursery-rows, being then managed as the seedlings.

When cuttings are employed, the strong young shoots of the year should be chosen in autumn or spring, and planted in a moist good soil; or any scarce sorts may be planted several together in pots, and plunged in a hot-bed, as they more readily strike root in that way.

These two last methods are the proper ones for raising the varieties with certainty.

These trees afford ornament and variety among other deciduous trees in the shrubbery, plantations, &c.

TINUS. See VIBURNUM.

TOAD-FLAX. See ANTIRRHINUM.

TOBACCO. See NICOTIANA.

TOLUIFERA, a genus comprising a plant of the exotic tree kind for the stove.

It belongs to the class and order *Decandria*

Monogynia, and ranks in the natural order of *Terebinthaceae*.

The characters are: that the calyx is a one-leaved perianth, bell-shaped, five-toothed, almost equal, with one angle more remote: the corolla has five petals, inserted into the receptacle, of which four are equal, linear, a little longer than the calyx; the fifth twice as big, obcordate: claw length of the calyx: the stamina have ten filaments, very short: anthers longer than the calyx: the pistillum is an oblong germ: style none: stigma acute: the pericarpium is a round berry, four-celled, four-seeded: the seed single, ovate.

The species is *T. Balsamum*, Balsam of Tolu Tree.

It is a tree of large size: the bark is very thick, rough, and of a brown colour: the branches spread out wide on every side: the leaves are alternate, oblong-ovate, four inches long, and two inches broad in the middle, rounded at the base, acuminate at the end, smooth, of a light green colour, on very short strong footstalks: the flowers are produced in small axillary racemes or bunches, each on a slender pedicel: the fruit roundish, the size of a large pea, divided into four cells, each containing one oblong-ovate seed. It is a native of Spanish America; and is the tree from which the Balsam of Tolu is made.

Culture.—This tree is raised from seeds, which should be obtained from its native situation, and be sown as soon as possible afterwards in pots of light earth, plunging them in the bark-bed of the stove. When the plants have three or four inches growth, they should be potted off separately, giving them water, and replunging them in the bed. They afterwards only require to be managed as other woody stove plants.

They afford variety in stove collections.

TOOTHACH TREE. See ZANTHOXYLUM.

TORCH-THISTLE. See CACTUS.

TOUCH-ME-NOT. See IMPATIENS and MOMORDICA.

TOURNEFORTIA, a genus containing plants of the shrubby exotic kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Asperifoliae*.

The characters are: that the calyx is a five-parted perianth, small: segments awl-shaped, permanent: the corolla one-petalled, funnel-form: tube cylindrical, globular at the base: border half-five-cleft, spreading: segments aminate, horizontal, gibbous in the middle: the stamina have five filaments, awl-shaped, at the

throat of the corolla: anthers simple, in the throat, converging, acuminate: the pistillum is a globular superior germ: style simple, length of the stamens, club-shaped: stigma circumcised, entire: the pericarpium is a globular berry, two-celled, perforated by two pores at top: the seeds four, subovate, separated by pulp.

The species cultivated are: 1. *T. hirsutissima*, Hairy Tournefortia; 2. *T. volubilis*, Climbing Tournfortia; 3. *T. foetidissima*, Fetid Tournfortia; 4. *T. humilis*, Dwarf Tournfortia; 5. *T. cymosa*, Broad-leaved Tournfortia; 6. *T. argentea*, Silvery Tournfortia; 7. *T. suffruticosa*, Hoary-leaved Tournfortia.

The first has a shrubby stem, somewhat scandent, branched, covered with a ferruginous shaginess: the leaves oblong, entire, nerved, hairy all over, but extremely so beneath: the spikes or racemes very much branched, stiff and straight, spreading a little: the flowers white, directed all one way. It is a native of the islands in the West Indies.

The second species has a twining woody stalk, which twists about the neighbouring trees for support, and rises to the height of ten or twelve feet, sending out several slender woody branches: the flowers are produced in branching spikes from the side and top of the branches; are small and white, and succeeded by small white succulent berries, having one or two black spots on each. It is a native of Jamaica, flowering in July and August.

The third has shrubby stems, ten or twelve feet high, sending out many branches: the leaves alternate, five inches long, two inches and a half broad in the middle, hairy on their under side, standing upon short foot-stalks: the branches are terminated by long branching spikes of flowers, ranged on one side; some of the foot-stalks sustain two, others three, others again four spikes of flowers, near five inches in length, reflexed at the top: the flowers are of a dirty white colour, small, and closely set; they are succeeded by small succulent fruit. It is a native of Jamaica.

The fourth species has low shrubby stalks, which seldom rise more than three feet high, sending out a few slender woody branches: the leaves are rough, dark green on their upper, but pale on their under surface: the flowers come out in single axillary spikes; are white, and succeeded by small succulent berries. It is a native of South America.

The fifth has the stem a fathom in height: the branches herbaceous, angular, grooved, smooth: the leaves ovate-lanceolate, long, petioled, smooth, wrinkled beneath: the flowers sessile,

on one side, disposed in two rows. It is a native of Jamaica, flowering in July.

The sixth species is a shrub, scarcely the height of a man: the trunk is very short, covered with a deeply cloven bark: the branches spreading very much, hirsute: the leaves at the ends of the branches, alternate, approximating into a rose as in *Sempervivum Canariense*, ovate or tongue-shaped, (being narrowed into the petiole,) sessile, rounded at the end, white all over, with a silky hairiness pressed close to them: the panicle large, divided into spikes, directed one way, and rolled back: the flowers snow-white. It is a native of the shores of the sea of Ceylon, &c.

The seventh has woody stalks which rise five or six feet high, from which spring out many slender woody branches: the leaves about two inches long, and an inch broad in the middle, rounded at each end with acute points; of a dark green on their upper surface, but having a white down on their under side, and sitting close to the branches: the flowers terminating and axillary, in slender branching spikes, which are recurved; and the flowers ranged on one side of them, white, and succeeded by small succulent berries. It is a native of Jamaica.

Culture.—These plants may all be increased by seeds, which should be procured from the countries where they grow naturally, and sown in small pots filled with light earth, and plunged into a hot-bed of tanners bark. They sometimes grow the first year, but often remain in the ground a whole year: therefore, when the plants do not come up the same season, the pots should be plunged in autumn into a tan-bed in the stove, where they should remain all the winter, and in the spring be removed and plunged into a fresh tan-bed, which will soon bring up the plants if the seeds were good. When these are fit to remove, they should be each planted in a small pot, and plunged into a tan-bed, where they must be shaded from the sun till they have taken new root, and then be treated in the same way as other tender plants from the same countries, which require to be kept constantly in the bark-stove. They may also sometimes be increased by cuttings, which should be planted in pots and plunged into the bark-bed.

They afford variety in stove collections.

TOXICODENDRON. See RHUS.

TRACES, LADIES'. See OPHRYS.

TRACHELIUM, a genus containing a hardy herbaceous plant of the perennial kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Campanaceae*.

The characters are: that the calyx is a five-

parted perianth, very small, superior: the corolla one-petalled, funnel-form: tube cylindrical, very long, very slender: border patulous, small, five-parted: segments ovate, concave: the stamina have five capillary filaments, length of the corolla: anthers simple: the pistillum is a three-sided-roundish inferior germ: style filiform, twice as long as the corolla: stigma globular: the pericarpium a roundish capsule, obtusely three-lobed, three-celled, opening by three holes at the base: the seeds numerous, very small.

The species cultivated is *T. caeruleum*, Blue Throatwort.

It has a perennial (biennial) fleshy, tuberous root, sending out many fibres which spread wide on every side: the leaves about two inches long, and one inch broad in the middle, ending in acute points: the stalks rise a foot and half high, with leaves on them shaped like those at the bottom; sometimes there are two pretty large leaves, and one or two smaller from the same point, or one large and three smaller; these come out alternate, and the upper part of the stalk, immediately under the umbel, is naked, except two or three narrow leaves, which are close to the foot-stalks of the flowers; these are disposed in form of an umbel composed of many small ones: the flowers are small, and of an azure blue colour, appearing in June and July. It is a native of Italy and the Levant.

Culture.—It is raised from seeds, which should be sown in the autumn when well ripened, or in the spring, in a bed or border of light mould. And when the plants are two or three inches in height, they should be set out in nursery rows six inches apart, to remain till the following autumn, when they should be planted out where they are to remain.

They afford ornament in rock-works, and other situations where the earth is poor.

TRADESCANTIA, a genus furnishing a plant of the hardy herbaceous perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Ensatae*.

The characters are: that the calyx is a three-leaved perianth: leaflets ovate, concave, spreading, permanent: the corolla has three orbicular petals, flat, spreading very much, large, equal; the stamina have six filiform filaments, length of the calyx, erect, villose, with jointed hairs: anthers kidney-form: the pistillum is an ovate germ, obtusely three-cornered: style filiform, length of the stamens: stigma three-cornered, tubulous: the pericarpium is an ovate capsule, covered by the calyx, three-celled, three-valved: the seeds few, angular.

The species is *T. Virginica*, Common Virginian Spiderwort, or Flower of a Day.

There are other species that may be cultivated.

It has roots composed of many fleshy fibres: the stalks smooth, rising a foot and half high: the leaves long, smooth, keeled, embracing: the flowers in clusters, composed of three large spreading purple petals; they appear early in June; and though each flower continues but one day, yet such is the profusion, that there is a succession of them through the greater part of the summer. It is a native of Virginia and Maryland, flowering in June.

There are varieties with deep blue flowers, with white flowers, with red flowers, and with purple flowers.

Culture.—They are readily increased by parting the roots, and planting them out in the autumn, or early in the spring, in a bed or border of common earth.

And also by seeds sown at the same seasons in similar situations, the plants being pricked out into other beds in the summer, and removed in the autumn to the places where they are to grow.

They afford ornament in the common borders among other flower plants.

TRAGOPOGON, a genus containing plants of the hardy, herbaceous, biennial, and perennial kinds.

It belongs to the class and order *Syngenesia Polygamia Aequalis*, and ranks in the natural order of *Compositae Semiflosculosae*.

The characters are: that the calyx is common simple, eight-leaved: leaflets lanceolate, equal, alternately interior, all united at the base: the corolla compound imbricate, uniform: corollets hermaphrodite, many, exterior ones a little longer: the proper one-petalled, ligulate, truncate, five-toothed: the stamina have five filaments, capillary, very short: anther cylindrical, tubulous: the pistillum is an oblong germ: style filiform, length of the stamens: stigmas two, revolute: there is no pericarpium: calyx converging, acuminate, length of the seeds, ventriculose, at length reflexed: the seeds solitary, oblong, attenuated to both ends, angular, rugged, terminated by a long awl-shaped down-bearing stipe: down feathered, flat, with about thirty-two rays: the receptacle naked, flat, rugged.

The species are: 1. *T. porrifolius*, Purple Goat's-beard, or Salsafy; 2. *T. pratensis*, Common Yellow Goat's-beard; 3. *T. crocifolius*, Crocus-leaved Goat's-beard; 4. *T. Dalechampii*, Great-flowered Goat's-beard.

The first has a biennial root, long, tapering or round-fusiform, that and the whole plant

 Sessile Trillium.

3 *Thalictrum aquilegifolium*
 Feathered Columbine.

abounding with a sweet milky juice, which soon turns to a brown resin, from the evaporation of its watery particles: the herb smooth, glaucous, about four feet high: the stem round, erect, branching, leafy: the leaves lanceolate, scarcely waved, ending in a tapering straightish point: the flowers solitary, terminating: the stalk which supports them tapering from the calyx downwards; of a purple colour.

It is cultivated in gardens under the name of Salsafy. The roots boiled or stewed have a mild sweetish flavour. The stalks are also cut in the spring, when they are four or five inches high, and dressed like Asparagus.

The second species has a biennial root, fusiform or fleshy tapering, abounding with milk, which is sweet not acrid: the whole herb smooth and very even: the stems several, branched, eighteen inches or two feet high, leafy, round, often tinged with purple: the branches elongated into a simple naked peduncle: the leaves alternate, sessile, some radical, others embracing the stem and branches, all broad and somewhat inflated at the base, but terminating in a long narrow point, which is flaccid or apt to hang down; very generally the margin towards the bottom is more or less waved or curled: the peduncles terminating, solitary, one-flowered, not swelling out at top, but of an equal thickness throughout: the flowers large and handsome, opening at day-break, and closing before noon. It is a native of Europe and Siberia, flowering in June.

The third resembles the first, but is scarcely a foot high: the leaves are villose at the base, but become smooth by age: the flowers violet, of two rows only, but in the middle rather yellow. It is a native of Italy and the South of France, and is biennial.

The fourth species has a perennial, thick and succulent root: the stems about a foot high, sometimes less: the leaves large, thick, villose, toothed and sinuated; the upper ones often entire: from the centre of the root-leaves, which spread in a rose, rises a naked thick flower-stalk, villose and thicker in the upper part, where it terminates in a very large flower of a pale yellow or sulphur colour. It is a native of Spain, and the South of France, &c. flowering from June to October.

Culture.—The first sort is only raised from seed, which should be sown in the spring, in an open situation to remain, either broad cast and raked in, or in shallow drills eight or nine inches asunder, scattering the seeds thinly, and covering them half an inch deep; and when the plants are come up two or three inches in height, they should be thinned and weeded by hand or

the hoe, leaving them eight or ten inches asunder, repeating the weeding as required during the summer, which is all the culture they require, and they will have large roots by the autumn, as September or October, when they may be begun taking up for use; and in November, when the leaves begin to decay, a quantity be preserved in sand for use in time of severe frost, when those in the ground cannot be got up.

In spring, when those remaining in the ground begin to shoot, the shoots, when a few inches high, may be cut for use, which, when quite young and tender, on being boiled, are excellent eating. A few plants should be suffered to run up to stalk every spring, to produce seeds.

The two following sorts may also be raised from seed in the same way, and the plants, when a little advanced in growth, be planted out if they are required for variety in any particular part.

The third sort may also be propagated by parting the roots in autumn and spring, and planting them where they are to remain.

The first is a culinary plant, and the others afford variety in the borders, &c.

TRAINED TREES, such young fruit-trees as are designed for walls and espaliers, being trained in the nursery to the intended form, by planting against any kind of walls, pales, reed-hedge, or other close fence; when a year old from the grafting or budding, training them in the manner of wall or espalier trees, for two, three, or more years, till they obtain a good spread of branches, and are arrived to a fruitful state, in order that those who are in haste to have their walls or espaliers covered at once with bearing trees, may have it accomplished in one season. The trees thus trained in the nursery, &c. on being planted out in autumn or spring to the places intended, cover the wall or espalier in some manner at once, and often bear fruit the ensuing summer.

In the nurseries large quantities of these sorts of trees are always kept ready trained for sale, particularly peaches, nectarines, and apricots for walls; in many places, also, cherries and plums, &c., also apples, pears, and other fruit-trees, for espaliers; and are proper to furnish the walls and espaliers of new gardens, and occasionally those of old ones, to bear fruit, till younger trees, planted untrained, become fruitful, or for supplying the places of old trees that fail, or bear bad fruit.

When it is intended to raise trained fruit-trees for walls and espaliers, a quantity of the best young plants of the respective sorts, dwarf and

half standards, of one year old, with the first shoots from the budding and grafting entire, should be planted out in autumn against some kind of fence in a free open situation, not less than four or five feet high, placing them from five or six to eight or ten feet distant, to remain for training. These in the spring following, just as they begin to make an effort for shooting, should be headed down, with a clean sloping cut upward, to within four, five or six eyes or buds of their origin, or place of insertion in the stock, especially those intended for dwarfs, and the half-standards, if worked on tall stocks; which prevents their running up too high with a single naked stem, and causes them to throw out lateral shoots from the lower part to fill the wall or espalier regularly with branches quite from the bottom upward; as they soon after push forth strong shoots from all the remaining lower buds, sufficient to give the tree its first proper formation as a wall tree, &c.; which shoots, when advanced in length in summer, should be trained along to the fence equally to the right and left, in a somewhat inclined position at full length till next spring, when these shoots may also be cut down to six or eight inches length, to force out a further supply of more branches near the bottom, as it is proper that they should be well furnished with branches below, in order to cover the wall, &c. well at the bottom part.

The summer's shoots should be shortened in this manner; more or less the two or three first springs, as may be necessary, in order to obtain a proper spread of lower branches to give the tree its intended form; though this work of pruning short to obtain laterals may also be performed occasionally in summer, in May or early in June, on the strong young shoots of the year, cutting or pinching them down to a few eyes; but the first is the best mode.

As the supply of branches thus obtained arrive at proper lengths, in the summer they should be all trained in along close to the wall, and if any fore-right or back shoots come out, they should be rubbed off close, leaving all the well-placed side and terminal shoots in every part, and letting the whole, or as many as possible, be trained in during this season, to have a plenty to choose from in the general pruning season, laying them in close to the wall, &c. equally to the right and left, on each side of the tree, in a spreading somewhat horizontal manner, no where crossing one another but at parallel distances, and mostly all at full length during the summer's growth, to remain till the general winter or spring pruning.

In the winter pruning, where more wood was trained up in summer than appears necessary,

or than can be trained in with due regularity, it should be retrenched, as well as any remaining fore-right or back shoots and other irregular growths omitted in summer, be now all pruned out, cutting them quite close to their origin. The whole should then be close nailed to the wall.

Having thus procured proper heads, they should afterwards be pruned according to the method peculiar to each respective sort, as directed under their culture, some requiring the branches to be shortened annually, others to be mostly trained at full length. See DWARF and ESPALIER TREES, PRUNING, &c.

The training of espalier trees is effected exactly in the same manner, only these may be trained as they stand in the nursery lines, in the open quarters or borders, &c. by ranging some stout stakes in the ground along one side of each tree, not in a continued straight range immediately the way of the row, but those of each tree ranged separate and obliquely, somewhat cross-ways the row as it were, that the branches of the different trees may range beside one another, and thereby have more room to extend the branches both ways, than the common distance in the nursery lines would admit, if ranged directly the way of the row.

It may be remarked that in general, unless good Trained Trees can be readily obtained, of from three or four to five or six years old, of a clean free growth, it will be better to plant entire young untrained trees of one or two years old, immediately from the nursery, putting them at once where they are to remain, managing them afterwards as the Trained Trees, to give them the proper form of head.

Some, in order to have as great a chance as possible, plant young untrained trees to remain, and Trained Trees of a bearing state, dwarfs and half-standards between, to cover the wall more effectually at once, and furnish a supply of fruit, until the young ones are trained and arrive at the bearing state; then, according as the trees of both sorts advance in that state of growth, those which appear the most prosperous are retained, and the others are gradually cut away, leaving the more thriving trees to occupy the wall wholly at last.

In most of the public nurseries, they raise Trained Trees for sale, which occupy all their close fences of walls, pales, &c. where they may be procured of almost any size, differing in price from three to five or ten shillings or more per tree, according to the sorts, age, and goodness of growth.

TRAILING ARBUTUS. See EPIGÆA.

TRAVELLER'S JOY. See CLEMATIS.

TREE CELANDINE. See BOCCONIA.

TREE GERMANDER. See TEUCRIUM.

TREE MALLOW. See LAVATERA.

TREE PRIMROSE. See OENOTHERA.

TREFOIL, SHRUBBY. See PTELIA.

TREFOIL, SNAIL. See MEDICAGO.

TREILLAGE, a sort of rail work consisting of ranges of light posts and railings, for the purpose of training espalier trees to, and occasionally for wall trees, where the walls do not admit of nailing the branches immediately against it; likewise for training wall-trees in forcing frames, &c. They are made in different ways, for use and ornament, as well as of different dimensions, from four or five to six or seven feet high.

For common espalier fruit-trees in the open ground, they are absolutely necessary, and may either be formed of common stakes and rails nailed together, or of regular joinery work.

The cheapest and the easiest, and soonest made Treillage for common espalier trees, is that formed with any kind of straight poles or stakes of underwood, as cut in the coppices, being then cut into proper lengths, and driven into the ground in a range at foot distances, all of an equal height, and then railed along the top with the same kind of poles, to preserve the whole straight and firm in a regular position. See ESPALIER.

And to render these still stronger, two or three horizontal ranges of rods may be nailed along the back part of the uprights, a foot or eighteen inches asunder.

The more elegant and ornamental Treillages are formed with regularly squared posts and rails of hard timber, neatly planed and framed together; having for this purpose deal or oak posts, uniformly worked two or three inches square; but if the main posts are of oak, it will be of advantage in respect to strength and durability, fixing the main posts in the ground ten or twelve feet asunder, with smaller ones between, ranging the horizontal railings from post to post in three or more ranges; the first about a foot from the bottom, a second at top, and one or two along the middle space, and, if convenient, one between each of the intermediate spaces; then fixing thin slips of lath, or the like, upright to the horizontal railing as far as the branches of the trees extend, ten inches or a foot asunder; and painting the whole white in oil colour, to render it more ornamental and durable. In training the trees, their branches are tied both to the railing of the Treillage, and the upright laths, according as they extend in length on each side. In either of the above cases, for an

espalier, five feet is generally of sufficient height, as, if much higher, the winds, having greater power, will loosen and displace them.

Where walls are built with large stones with the joints irregular and far asunder, and which do not afford opportunities, like brick walls, for nailing properly in the regularity which is required, a neat Treillage is sometimes uniformly erected all along close to the wall, to train and nail or tie the branches to in a regular manner.

These may be made of coarse pieces of battens, railings, &c. or of such as are wrought in a neat manner, according to the convenience and taste of the person who has them.

In frames and stoves, where wall trees are intending for forcing, as they are planted both against the back wall, and occasionally in a detached low range forward towards the middle or front space, Treillages are indispensably necessary upon which to arrange the branches of the trees in a regular expansion, not to train them immediately close to the wall of the flues of that department, but detached several inches, and formed with light neat squared upright battens, and small horizontal rails, uniformly framed together in a light open manner.

TREILLIS, a term sometimes employed to signify the same as treillage. See TREILLAGE.

TRILLIUM, a genus furnishing plants of the low, tuberous-rooted, flowery, perennial kind.

It belongs to the class and order *Hexandria Trigynia*, and ranks in the natural order of *Sarmentaceae*.

The characters are: that the calyx is a three-leaved perianth, spreading: leaflets ovate, permanent: the corolla has three petals, subovate, a little bigger than the calyx: the stamina have six awl shaped filaments, shorter than the calyx, erect: anthers terminating, oblong, length of the filaments: the pistillum is a roundish germ: styles filiform, recurved: stigmas simple: the pericarpium is a roundish berry, three-celled: the seeds many, roundish.

The species are: 1. *T. cernuum*, Drooping Trillium; 2. *T. erectum*, Upright Trillium; 3. *T. sessile*, Sessile-flowered Trillium.

The first has a perennial tuberous root: the stem is erect, a foot high, simple, round, slightly striated, smooth: the leaves three together, terminating, on short footstalks, spreading, rhomboidal, pointed, entire, veiny, smooth, paler beneath: the flowers solitary, among the leaves, without bractes: the flower-stalk round, a little waved, smooth. It is a native of North America.

The second species has a taller stalk: the three

leaves are placed at a distance from the flower, which stands upon a long footstalk, and is erect: the petals are purple, larger, and end with sharper points. It is a native of Virginia, Canada, &c.

The third has a purple stalk: the three leaves grow at the top like the first; but they are much longer, and end in acute points: the petals are long, narrow, and stand erect; are of a dark brownish red: the calyx leaves are streaked with red: the leaves mottled. It grows in Carolina and Virginia.

Culture.—These plants may be increased by seeds, which should be sown on a shady border as soon as they become ripe in the autumn: when they appear in the spring, the plants should be kept clean from weeds, and in the autumn following be planted out where they are to remain and flower.

They succeed best in a light soil, where the situation is rather shaded.

They afford variety in such places.

TRIUMFETTA, a genus furnishing plants of the shrubby and herbaceous kinds.

It belongs to the class and order *Dodecandria Monogynia*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a five-leaved perianth: leaflets lanceolate, arched below the tip, deciduous: the corolla has five petals, linear, erect, obtuse, concave, bent back, awned below the tip: the stamina have sixteen filaments, equal, ascending, length of the corolla, awl-shaped, erect; anthers simple: the pistillum is a roundish germ: style length of the stamens: stigma bifid, acute: the pericarpium is a globular capsule, fenced on every side with hooked prickles, four-celled: the seeds two, convex on one side, angular on the other.

The species cultivated are: 1. *T. Lappula*, Prickly-seeded Triumfetta; 2. *T. annua*, Annual Triumfetta.

The first rises with an upright stem to the height of six or seven feet; towards the bottom it becomes woody, and at top divides into four or five branches: the leaves placed alternately the whole length of the stem, about two inches and a half long, and almost two inches broad near the base, divided almost into three lobes toward the top, and the middle division ending in an acute point; they are veined on their under side, are covered with a soft brown down, and have several nerves running from the midrib to the sides; their upper side is of a yellowish green, and a little hairy; their borders are acutely but unequally serrate, and stand upon footstalks an inch in length: the branches are terminated by long spikes of flowers, which

come out in clusters from the side of the principal footstalk, at the distances of about an inch: the flowers are small, the petals narrow and of a yellow colour; they are, succeeded by burry capsules, round, and with long prickles placed on every side. It is a native of Jamaica, Martinico, &c. flowering in July and August.

The second species is an annual plant, rising about two feet and a half high, and sending out several branches on every side: the leaves ending in long acute points; some are heart-shaped, others have an angle on each side towards the point; they are from three to four inches long, and almost as much in breadth where broadest; they stand upon very long footstalks, and are notched on their edges: the flowers come out in long loose spikes at the top of the plant; are small and yellow. It is a native of India, flowering in September.

Culture.—This is increased by seeds, which must be procured from its native place, and be sown on a hot-bed, or in pots plunged in the bark-bed of the stove: when the plants have one or two inches growth, they should be removed into separate pots, replunging them in the bark-bed till well re-rooted.

They afterwards require to be kept constantly in the stove, or hot-house, and to have the management of other ligneous plants of the stove kind.

They produce variety in stove collections.

TROPÆOLUM, a genus furnishing plants of the herbaceous, annual, and perennial, trailing and climbing kinds.

It belongs to the class and order *Octandria Monogynia*, and ranks in the natural order of *Trihilatae*.

The characters are: that the calyx is a one-leaved perianth, five cleft, from upright spreading, acute, coloured, deciduous; the two lower segments narrower; horned at the back with an awl-shaped, straight, longer nectary: the corolla has five petals, roundish, inserted into the divisions of the calyx; two upper sessile; the others lower, with oblong, ciliate claws: the stamina have eight awl-shaped filaments, short, declining, unequal: anthers erect, oblong, rising: the pistillum is a roundish germ, three-lobed, striated: style simple, erect, length of the stamens: stigma trifid, acute: the pericarpium berries (or nuts) somewhat solid, three, on one side convex, grooved and striated; on the other angular: the seeds three, gibbous on one side, angular on the other, roundish, grooved and striated.

The species cultivated are: 1. *T. minus*, Small Indian Cress, or Nasturtium; 2. *T. majus*, Great Indian Cress, or Nasturtium.

Trollius Americanus
American Globe flower

Tropaeolum majus
Greater Nasturtium

The first has an herbaceous, trailing stem: the leaves almost circular, smooth, grayish: the flowers axillary, on very long peduncles; composed of five acute-pointed petals, the two upper large and rounded, the three under narrow, jointed together at bottom, and lengthened out into a tail two inches long.

There are varieties with deep orange-coloured flowers inclined to red, with pale yellow flowers, and with double flowers.

The second species is larger in all its parts: the borders of the leaves are indented almost into lobes; and the petals are rounded at the top. The fruit consists of three berries, becoming juiceless when ripe, fungous, deeply grooved and wrinkled, gibbous on one side, angular on the other, narrowing upwards. It begins to flower in July, and continues till the approach of winter.

There are varieties with pale yellow flowers, orange-coloured flowers, and the double-flowered.

They are both natives of Peru, and commonly esteemed to be annual plants, though they may be continued through the winter, if they are kept in pots, and sheltered in a green-house or glass case, in like manner as the variety with double flowers.

The stalks will climb six or eight feet high, when they are trained up, and thus the flowers make a good appearance; but when they trail upon the ground, they will spread over the neighbouring plants and become unsightly: the flowers are frequently eaten in salads; they have a warm taste like the garden cress, and hence the plant has its common name of *Nasturtium*; they are likewise used for garnishing dishes: the seeds are pickled, and by some are preferred to most pickles for sauce, under the false name of capers.

Culture.—These plants in all the single varieties may be increased by seeds, which should be sown in the spring in patches where they are to flower in the borders, or in drills in the garden.

They afterwards only require to be kept free from weeds, and to be well supported by sticks.

The double variety must be increased by planting cuttings of the branches in pots of light mould in the early part of summer, placing them in the shade, and giving frequent light waterings: those planted early may be rendered more forward by being plunged in a moderate hot-bed.

It requires to be protected in the green-house in the winter, being well supported with sticks.

They all afford variety in the borders, clumps, &c. in the summer, and the double sorts among potted plants.

TROWEL, GARDEN, a trowel made of iron, in a hollow or scooped form, which is an

useful implement in taking up numerous sorts of small plants and bulbous roots, and replanting them in pots, sowing in patches, and various other similar light works: it should be from six to twelve inches long in the plate, and half as broad, and fixed on a short handle, to hold with one hand. From its being hollowed semi-circularly, it is remarkably handy in removing many sorts of small plants with a ball or lump of earth whole about their roots, so as not to feel their removal; lifting several sorts of bulbous flower roots, after the flowering is past in summer; planting bulbs in patches or little clumps about the borders, and also for digging small patches in the borders for sowing hardy annual flower-seeds on; likewise for filling mould into small pots in planting any sort of plants, stirring the surface of the mould in pots, and fresh earthing them when necessary: it is also highly useful for filling in earth about plants in hot-beds, and under frames, or any small compartments where a spade cannot be readily introduced.

They should be had of different sizes to suit different purposes.

TRUMPET FLOWER. See *BIGNONIA*.

TRUMPET HONEYSUCKLE. See *LONICERA*.

TUBEROUS ROOTS, such as consist of one or more swelled or knobbed tubers, of a solid fleshy substance.

In this tribe are comprised many plants of the ornamental flowery kind, and some esculents of the kitchen garden; as in the former anemone, ranunculus, filipendula, many sorts of iris, aconitum, pæony, orchis, cyclamen, winter-aconite, day lily, &c. some also with bulbo-tuberous roots, as gladiolus, polyanthes, or tuberose, ophrys, &c. and of the esculent tuberous roots are the potatoe and Jerusalem artichoke; all of which plants are principally perennial in their roots, being perpetuated annually by offsets.

TUBS, a sort of boxes calculated for containing large green-house exotics, and other potted plants and trees when grown too large for the pots.

Green-house plants, particularly in some of the larger-growing sorts, in a few years growth become too large to be contained longer in pots, even in those of the largest size; which being sometimes both too small for the increased roots of the plants, and of insufficient strength to admit of moving them with the plants, as large orange and lemon-trees, myrtles, oleanders, and other tree kinds, as well as large plants of the great American aloe, &c.: when any of these, or other similar large-growing trees and plants, are advanced considerably in size in their general

growth; some proper strong tubs of larger dimensions than the pots containing the plants should be prepared in proper time, in which to shift them.

These tubs are made by the coopers proper for this purpose, somewhat in the garden-pot form, a little wider at top than at bottom, from a foot and half to two and a half deep; the width in proportion; constructed of the strongest thick staves and bottoms, and well hooped with iron, and with two iron handles at top, by which to remove them; these handles being strong and generally hooked, especially in very large tubs, in order to receive a pole in each occasionally, that the tub and plant together may be more readily moved: the bottom of the tubs have auger holes bored in different parts, at regular distances, by which to discharge the superfluous moisture after watering, &c.

In tubbing large-grown plants, they should be removed from their present pots, with the balls of earth about the roots entire; and having earthed the bottom parts of the tubs, the plant should be set in with its whole ball of earth, filling up properly around, and an inch or two over the top of the ball with more fresh mould, and then watering. See SHIFTING PLANTS and POTTING.

TULIPA, a genus furnishing plants of the bulbous-rooted, flowery perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Coronariæ*.

The characters are: that there is no calyx: the corolla bell-shaped: petals six, ovate-oblong, concave, erect: the stamina have six awl-shaped filaments, very short: anthers quadrangular, oblong, erect, distant: the pistillum is a large germ, oblong, from three-cornered round: style none: stigma three-lobed, triangular: angles protuberant, bifid, permanent: the pericarpium is a three-sided capsule, three-celled, three-valved: valves ciliate at the edge, ovate: the seeds numerous, flat, incumbent in a double row, semicircular, separated by similar flocks.

The species cultivated are: 1. *T. Gesneriana*, Common Garden Tulip; 2. *T. sylvestris*, Wild or Yellow Tulip.

The first has the stem nearly upright or bending a little, taller and stronger than in the second, from a foot to eighteen inches in height: the leaves three, four, or five, embracing, doubled, lanceolate, acute, nerved, glaucous; the lowest near the bulb two inches and a half wide, the others gradually narrower: the flower large, erect, in a wild state most commonly red with a black base: petals ovate, blunt, smooth: the anthers commonly very dark-coloured or black;

the stigma three-lobed, each lobe bifid, bent back, and the edge curled back: the capsule superior, of a triangular prismatic form, three-grooved, transversely striated: the valves having a partition in the middle, and ciliate at the sutures with white silky vibrissæ turned inwards: the seeds obovate, narrowed towards the navel, flat on both sides, margined, rufescent, fastened horizontally in a double row to the central margin of the partitions. Before the fruit is fully ripe, the vibrissæ in this genus are glued together into three thin membranes, which being interposed between the columns of seeds, make the unripe capsules six-celled. It is a native of many parts of the Levant.

It is distinguished from the other, according to Martyn, by "its pubescent scape, spreading sweet-smelling corolla, the earliness of its flowering, and the smallness of its size."

In respect to the varieties, the editor of Miller's Dictionary observes, that "the old authors divided Tulips into *Præcoces* or Early-blowers, and *Serotinae* or Late-blowers, with an intermediate division of *Dubiae Mediæ*, Doubtful or Middle-blowers, which flowered between the two others, and for the most part rather belonged to the late-blowers. Modern florists," he says, "have almost neglected the early-blowers."

The first sort, according to Miller, "are not near so fair, nor do they rise half so high as the late ones; they are chiefly valued for appearing early in the spring: some of them will flower the middle of March in mild seasons, if planted in a warm border near a wall or other shelter, and others will succeed them, so that they will keep flowering until the general season for these flowers is come, which is towards the end of April.

"The several varieties of these early-blowing Tulips rise to different heights in their stems, and scarcely any two of them are equal. The Duke Van Toll, which is one of the first that appears in the spring, is generally very short-stalked, and the others in proportion to their earliness are shorter than those which succeed them; and the late-blowers are all considerably longer in their stems than any of the early-blowers.

"The late-blowing Tulips producing much finer flowers than the early ones, have engrossed almost the whole attention of the florists. It would be to little purpose to enumerate all the varieties, since there is scarcely any end of their numbers, and what some value at a considerable rate, others reject; and as there are annually many new flowers obtained from breeders, those which are old, if they have not very good properties to recommend them, are thrown out and despised."

It is observed that "modern florists in Holland and Flanders, and our English florists from them, boast a prodigious variety of late-blowing Tulips." And that "Mr. Maddock of Walworth, in his catalogue of flowers for 1792, has no less than about 665 of these admired beauties, all ranged under their proper families and colours, with their names and prices: besides the early sorts, *double tulips*, *parrot-tulips*, *French tulips*, and *breeders*."

It is added that "the late-blowers are distributed into five families: 1. *Primo Baguets*; very tall; fine cups with white bottoms, well broken with fine brown, and all from the same breeder: 2. *Baguet Rigauts*; not quite so tall, but with strong stems, and very large well-formed cups with white bottoms, well broken with fine brown, and all from the same breeder: 3. *Incomparable Verports*; a particular kind of *Bybloemens*, with most perfect cups, very fine white bottoms, well broken with shining brown, and all from the same breeder; some of these are from two to five guineas a root: 4. *Bybloemens*; with bottoms white, or nearly so, from different breeders, and broken with variety of colours; those of the Verports are cherry and rose: 5. *Bizarres*; ground yellow, from different breeders, and broken with variety of colours.—These barbarous terms, used by the Dutch florists, are, it is said, a mixture of Dutch and French. Baguet is from the French Baguette, a rod or wand, so named from its tall slender stem. Bizarre is also French; and the Tulips of that family have the name from the variety and irregularity of their colours. Rigauts are probably from the name of some eminent florist, Rigaud. The other terms are Dutch.—Breeders are of one colour, and when broken produce new varieties."

"The properties of a fine variegated late Tulip, according to the best modern florists, are," he says, "these: 1. the stem should be strong, upright, and tall, about thirty inches high: 2. the flower should be large, composed of six petals, proceeding a little horizontally at first, and then turning upwards so as to form an almost perfect cup, with a round bottom, rather wider at the top: 3. the three outer petals should be rather larger than the three inner ones, and broader at their base: all the petals should have the edges perfectly entire; the top of each should be broad and well rounded; the ground colour at the bottom of the cup should be clear white or yellow; and the various rich stripes which are the principal ornament of a fine flower should be regular, bold, and distinct on the margin, and terminate in fine broken points, elegantly feathered or pencilled: 4. the centre of each

VOL. II.

petal should contain one or more bold blotches or stripes, intermixed with small portions of the original colour, abruptly broken into many irregular obtuse points. Some florists," he adds, "are of opinion that the central stripes or blotches do not contribute to the beauty of the Tulip, unless they are confined to a narrow stripe exactly down the centre; and that they should be perfectly free from any remains of the original colour: it is certain that such flowers appear very beautiful and delicate, especially when they have a regular narrow feathering at the edge: but it is unanimously agreed, that the Tulip should abound in rich colouring, distributed in a distinct and regular manner throughout the flower, except in the bottom of the cup, which should indisputably be of a clear bright white or yellow, free from stain or tinge, in order to constitute a perfect flower. The Double and Parrot Tulips are," says he, "in no sort of esteem among the florists."

The second species has the bulb ovate, gibbous: the stem quite simple, nearly upright, round, smooth, leafy in the middle, attenuated at the base: the leaves alternate, slightly embracing, lanceolate, acute, keeled, glaucous: the flower always yellow, greenish on the outside: the petals elliptic-lanceolate, without any nectary: the filaments flattened: the anthers terminating, versatile, oblong: the germ three-cornered: stigma sessile, three-cornered. A native of the South of Europe, &c., flowering in April.

"It has most of these characters in common with the Garden species; but the circumstances that abundantly distinguish this are; the narrow leaves, the nodding flower, the hairiness at the base of the stamens and on the tips of the petals, and especially the simple obtuse form of the stigma, which is totally different from that of the Garden Tulip: the flower too is fragrant; the pollen yellow, not black; and the anthers remarkably long. In the *Flora Danica* they are represented short and round."

Culture.—All the different sorts of tulips may be increased by offsets from the roots, and by sowing seeds to produce new varieties. The offsets should be separated from the old roots in June, on taking them up when the flowering is over, planting them in nursery-beds, in rows six inches apart, and to the depth of three, four, or five, in the beginning of autumn. They may also in the old root, be planted in beds, or in the borders or other parts where they are to remain and blow, in patches of four or five, placed irregularly; and to have a succession, they may be planted at different times; they are usually planted with a blunt dibble: the new roots should always be planted by themselves.

The early and late sorts should likewise be each put in, in places by themselves, and it is advised that the roots of the early blowing kinds should be planted the beginning of September, in a warm border, near a wall, paling, or hedge; as, when they are put into an open spot of ground, their buds are in danger of suffering by morning frosts in the spring. The soil for these should be renewed every year, where people intend to have them fair. The best soil for this purpose is that which is taken from a light sandy pasture, with the turf rotted amongst it, and to this should be added a fourth part of sea sand. This mixture may be laid about ten inches deep, which will be sufficient for these roots, which need not be planted more than four or five inches deep at the most.

The offsets should not be planted amongst the blowing roots, but in a border by themselves, where they may be set pretty close together, especially when they are small; but these should be taken up when their leaves decay, in the same manner as the blowing roots, otherwise they would rot if the season should prove very wet, as they are not so hardy as the late blowers, nor do they increase half so fast, so that more care is requisite to preserve the offsets of them.

When these sorts come up in the spring, the earth upon the surface of the beds or borders should be gently stirred and cleared from weeds; and as the buds appear, if the season should prove very severe, it will be of great service to cover them with mats, for want of which, many times they are blighted, and their flowers decay before they blow, which is often injurious to the roots, as is also the cropping of the flowers soon after they are blown; as their roots, which are formed new every year, are not at that time arrived to their full magnitude, and are of course deprived of proper nourishment or support.

When these flowers are blown, if the season should prove very warm, it will be proper to shade them with mats, &c., in the heat of the day; and when the nights are frosty, they should be covered in the same manner, by which means they may be preserved a long time in beauty; but when their flowers are decayed, and their seed-vessels begin to swell, they should be broken off just at the top of the stalks, as when they are permitted to seed it injures the roots very greatly.

In these sorts when the leaves are decayed, which is usually before the late blowers are out of flower, their roots should be taken up, and spread upon mats in a shady place to dry; after which they should be cleared from filth, and put in a dry place where vermin cannot come to them, until the season for planting

them again, being very careful to preserve every sort separate, that it may be known how to dispose of them at the time of planting.

For this purpose, it is a good method to have large flat boxes made, which are divided into several parts by small partitions, each of which is numbered the same as the divisions of the beds; so that when a catalogue of the roots is made, and the numbers fixed to each sort in the beds, nothing more is necessary, in taking up the roots, but to put every kind into the division marked with the same number in the bed. This saves a great deal of trouble in making fresh marks every time the roots are taken up, and effectually answers the purpose of preserving the kinds separate and distinct.

In raising these plants from seed, it is, from the time of sowing, seven or eight years before they produce flowers; and after all, they at first appear only single-coloured, often requiring two, three, or more years longer before they break into different colours or variegations; so that the tediousness of raising seedling tulips to a flowering state often deters from the undertaking. It is, however, the method by which all the fine varieties were first obtained, and by which new varieties are still annually gained; as many persons sow some every year, in expectation that after the first six or seven years a new show of flowers will be produced, out of which many new varieties may annually discover themselves in each parcel. It is by this process the Dutch are so famous for furnishing such an infinity of fine varieties, supplying almost all other countries.

In effecting this business, great care should be used in the choice of the seed: the best is that which is saved from breeders which have all the good properties before related, for the seeds of striped flowers seldom produce any thing that is valuable; and the best method to obtain it is to make choice of a parcel of such breeding Tulip roots as are wished to save seeds from, and place them in a separate bed from the breeders, in a place where they may be fully exposed to the sun, planting them at least nine inches deep, as when they are planted too shallow their stems are apt to decay before their seed is perfectly ripened: the flowers should be always exposed to the weather, as when they are shaded with mats, or any other covering, it prevents their perfecting the seed. About the middle of July, according to the season, the seeds will be fit to gather, as shown by the dryness of their stalks and the opening of the seed-vessels, at which time they may be cut off, and the seeds be preserved in the pods till the season for sowing, being careful to put them up in a dry place, otherwise they will be subject to

mould, and be rendered useless. The beginning of September is the proper season for sowing the seed; for which there should be provided a parcel of shallow seed-pans, or boxes, which should have holes in their bottoms to let the moisture pass off; these should be filled with fresh sandy earth, laying the surface very even, upon which the seeds should be sown thinly as regularly as possible; some of the same light sandy earth being sifted over them, about half an inch thick. These boxes or pans should be placed where they may have the morning sun till eleven o'clock, in which situation they may remain until October, at which time they should be removed into a more open situation, where they may enjoy the benefit of the sun all the day, and be sheltered from the north winds, where they should remain during the winter season; but in the spring, when the plants appear with grassy leaves, they should be again removed to their first situation; and if the season be dry they must be refreshed with water while the plants remain green; but as soon as their tops begin to decay, no more should be given. The boxes should be placed in a shady situation during the summer season, but not under the drip of trees. The weeds and moss should be kept constantly cleared off from the surface of the earth in the boxes, and a little fresh earth be sifted over them soon after their leaves decay; and at Michaelmas they should be fresh earthed again, and as the winter comes on be again removed into the sun as before, and treated in the same manner, until the leaves decay in the spring, when the bulbs should be carefully taken up, and planted in beds of fresh sandy earth, which should have tiles laid under them, to prevent their roots from shooting downward, which they often do when there is nothing to stop them, and are destroyed. The earth of these beds may be about five inches thick upon the tiles, which will be sufficient for nourishing the roots while young. The distance of planting them need not be more than two inches, nor should they be planted above two inches deep. Toward the end of October, it will be proper to cover the beds over with a little fresh earth about an inch deep, which will preserve the roots from the frost, and prevent moss or weeds from growing over them; and when the winter is very severe, it may be proper to cover the bed either with mats or peas-baulm, to prevent the frost from entering the ground, as these roots are much tenderer while young, than after they have acquired strength. In the next spring the surface of the ground should be again gently stirred to make it clean, before the plants come up; and when the spring proves dry, they

must be frequently refreshed with water in small portions during the time of their growth; and when the leaves are decayed, the weeds should be taken off, and the beds covered with fresh earth, as before, which should also be repeated again in the autumn. When the bulbs have been managed in this way two years, they should in the summer following, when their leaves decay, the roots being by that time considerably improved in growth, be again taken up, and planted in a fresh prepared bed, in drills three or four inches asunder, in which to remain two years longer; then, at the decay of the leaf, be again planted out into fresh beds, in rows as before, where they should be let remain to blow, being afterwards ordered as the flowering bulbs. When they are in full flower, they should be examined, in order to mark such of them as discover the best properties, that they may be separated from the others at the proper lifting season, and be replanted in beds by themselves for breeders; removing them annually at the proper season into different beds of opposite or contrary soils, as one year in poor hungry earth, the next in a much richer mould; continuing them so till they break into variegations and stripes of different colours, which are the only modes by which it can be assisted. When the leaves and flower-stems are decayed and withered, and the roots have ceased growing and drawing nourishment from the earth, it is the proper period for lifting or taking the old roots out of the earth, to reserve them till autumn for planting, being preserved in the manner directed above.

The early dwarf sorts are the most proper for forcing for early blowing, and also for being placed in glasses, in rooms, &c.

The second species may be managed in the same manner. They are all highly ornamental flowers, from their much varied and most beautiful colours.

TURF, the green surface or sward cut from pastures, &c., for the purpose of laying down grass-grounds; as lawns, plats, bowling-greens, &c.

It is flayed with the turfing-iron, in regular lengths of two or three feet, and a foot wide; and being properly laid down close and regular in the places intended, it immediately forms an even grass sward, which quickly strikes root in the ground, in proper growth and verdure. This sort of work may be performed any time in autumn, winter, and spring, in open weather, or occasionally in summer, in a moist season, but the autumn is the best season. The best turf is mostly procured from fine close fed pastures, commons, or downs, &c., where the sward is close and even; or that of any grass

field of similar close firm sward, where the grass is not rank and coarse, nor abounding in weeds; or much overrun with the common wild daisy. but should this be omitted, the first heavy rain will mostly recover the whole effectually, and swell the sward, so as to close all the chasms, and revive the verdure of the grass plants, when

In the operation of cutting, a line should be drawn tight lengthways of the grass-ground, and then the cutting-racer be stricken into the surface of the sward, close to the line, pushing it along so as to cut or score the sward in a straight line, about an inch and half deep; and having thus raced out one length, the line should be moved a foot width further to race out another length as before, proceeding in the same manner to a third, and so on to as many lengths of the line, in foot widths, as the surface may be necessary; then, by the same means, the sward is to be raced cross-ways in yard distances, performed before the grass gets too high and thus the proper widths and lengths are formed. After the sward has been thus raced

half deep; and having thus raced out one length, the line should be moved a foot width further to race out another length as before, proceeding in the same manner to a third, and so on to as many lengths of the line, in foot widths, as the surface may be necessary; then, by the same means, the sward is to be raced cross-ways in yard distances, performed before the grass gets too high and thus the proper widths and lengths are formed. After the sward has been thus raced

out, it should be flayed, or cut up with the *TURFING-IRON*, an implement made use of for flaying or cutting up grass turf from land only longways the whole length of each raced. It is formed with an iron plate for the cutter, six to seven or eight inches following immediately after to roll them wide, a little rounding forward at the edge, half in yard lengths, grass side inward, which is thin and sharp for cutting, but thick and tight as possible; having thus cut one gradually behind to the upper part, where proceed with another in the same it is forged to a long bent iron handle, the bend continue with the whole. As they should be piled resting flat with its back on the ground, in the either, ready for carrying proper position for readily cutting or flaying the hundred, as is often turf evenly, all a regular depth; the handle at the top, for the fix a short wooden handle of that kind. It is represented at fig. 4. in the annexed plate. In using it in cutting the turf, the workman takes hold with one hand in the top handle, the other below, or with the latter guiding the tool in the proper position, whilst the upper hand is placed against his knee, &c., which assists him in thrusting it forward into the ground evenly under the sward; and thus he proceeds along in a regular manner, moving the tool gradually along at each level and even, at an equal depth.

genus comprising a plant of exotic kind, for the

and order *Pentandria*

the natural order of

calyx is a one-

alous: tube

der erect,

h of the

care in this part of the business, except occasionally beating down any swelling inequalities, and sometimes rolling it with a heavy iron roller. Sometimes when turf is laid in the summer, or early part of autumn, in dry hot weather, it will shrink and open considerably at the joinings, and assume a decayed-like appearance. In this case, a few good waterings would be serviceable; five-parted: segments lanceolate, length

T U R

tube: the corolla has five petals, obcordate, acuminate, flat, from upright spreading: claws narrow, inserted into the tube of the calyx: the stamina have five awl-shaped filaments, shorter than the corolla, inserted into the tube of the calyx: anthers acuminate, erect: the pistillum is a conical germ: styles three: filiform, length of the stamens: stigmas capillaceous-multifid: the pericarpium is an ovate capsule, one-celled, three-valved: receptacles annexed to the valves longitudinally, linear: the seeds numerous, oblong, obtuse.

The species cultivated is *T. ulmifolia*, Elm-leaved Turnera.

It has a shrubby stem, eight or ten feet high, sending out branches on every side the whole length: the leaves ovate-lanceolate, two inches and a half long, and an inch and half broad, rough on their upper side, and of a lucid green; their under side has many strong veins, and is of a lighter green, the edges are serrate: the flowers sit close upon the footstalks of the leaves, having two pretty large leafy appendages to the calyx: the corolla is large, and of a bright yellow. It is a native of the West Indies.

There is a variety with narrow leaves, which rises with a shrubby stalk to the height of eight or ten feet, with branches less slender and stiff

T W A

than in the broad-leaved sort: the leaves narrow-lanceolate, hairy, near three inches long, and about three quarters of an inch broad, terminating in acute points, obtusely serrate on their edges, and standing upon very short footstalks; when rubbed, they emit a disagreeable odour: the flowers are of a pale yellow: the petals large and oval, with the tails or claws twisted and joining: they are not so large or of so bright a yellow as in the true Elm-leaved sort. It is a native of Jamaica.

Culture.—These plants are easily raised from seed, which should be sown in the spring, in pots, and plunged in the bark-bed, or any other hot-bed, under glasses; and when the plants are come up two or three inches in height, they should be planted separately in small pots, plunging them in the stove of the bark-bed, to forward them a little in growth: they may afterwards be placed in any part of the stove, and be managed as other stove exotic plants. They are also capable of being increased by cuttings, planted in pots, and forwarded in the above manner. They afford a good variety among stove plants.

U L E

ULEX, a genus furnishing shrubby plants of the thorny kind.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a two-leaved perianth, permanent: leaflets ovate-oblong, concave, straight, equal, a little shorter than the keel: upper leaflet two-toothed, lower three-toothed: the corolla papilionaceous, five-petalled: standard obcordate, emarginate, erect, very large: wings oblong, obtuse, shorter than the standard: keel two-petalled, straight, obtuse, converging by the lower margin: the stamina have diadelphous filaments, simple and nine-cleft: anthers simple: the pistillum is an oblong germ, cylindrical, hirsute: style filiform, rising: stigma obtuse, very small: the pericarpium is an oblong legume, turgid, scarcely longer than the calyx, straight, one-

U L E

celled, two-valved: the seeds few, roundish, emarginate.

The species cultivated are: 1. *U. Europæus*, Common Furze, Whin, or Gorse; 2. *U. nanus*, Dwarf Furze; 3. *U. Capensis*, Cape or African Furze.

The first is a well known shrub, which has its branches very close, deeply furrowed, woolly or hirsute, full of thorns, which are stretched out, branched, angular, very sharp, smooth, evergreen, leafy, frequently flower-bearing; according to Withering, awl-shaped, a little bowed downwards, woolly at the base, yellow at the ends: the leaves at the base of the spines and spinules, solitary, awl-shaped, terminating in sharp yellowish thorny points, somewhat rugged, often hirsute, deciduous: the peduncles axillary, single or two together, one-flowered, villose: the flowers of a fine yellow or gold colour. It is a native of Britain.

U R T

which are taper, stiff, and have a dark-green bark: the leaves about two inches and a quarter broad, dark-green above, and pale-green beneath, upon pretty long footstalks: the flowers axillary, solitary, sessile, shaped like those of the Mallow, but small and of a deep blush colour. It is a native of China, flowering here in July and August.

The second species has a suffruticose stem, upright, three feet high, with ascending branches: the leaves sinuate-palmate, with obtuse sinuses, serrate, rough, alternate, petioled, having a single glandular pore on the middle rib underneath: the flowers are rose-coloured, small, subsolitary, axillary. It is a native of the East Indies.

Culture.—These plants may be increased by seeds, which should be sown on a hot-bed, or in pots plunged into it, in the early spring season. When the plants have some growth, they should be removed into separate pots, being replunged in a fresh hot-bed, requiring afterwards the same management as tender exotic plants. When placed in the stove in the spring, they ripen seeds the first year, but otherwise in the second, and seldom continue longer.

They afford variety among other stove plants.

URTICA, a genus furnishing plants of the hardy herbaceous kind.

It belongs to the class and order *Monoecia Tetrandria*, and ranks in the natural order of *Scabridæ*.

The characters are: that in the male flowers the calyx is a four-leaved perianth: leaflets roundish, concave, obtuse: the corolla petals none: nectary in the centre of the flower, cup-shaped, entire, narrower below, very small: the stamina have four awl-shaped filaments, length of the calyx, spreading, each within each calyx-leaf: anthers two-celled: female flowers either on the same or a distinct plant: the calyx is a two-valved perianth, ovate, concave, erect, permanent: there is no corolla: the pistillum is

U R T

an ovate germ: style none: stigma villose: there is no pericarpium: calyx converging: the seed one, ovate, blunt, compressed, shining.

The species cultivated are: 1. *U. cannabina*, Hemp-leaved Nettle: 2. *U. Canadensis*, Canada Nettle: 3. *U. nivea*, Chinese or White-leaved Nettle.

The first has a perennial root: the stems five or six feet high: the leaves oblong, deeply cut into three lobes, which are acutely indented on their edges, and placed on long petioles: the flowers axillary in long cylindrical catkins: males on the lower part, females on the upper. It is a native of Siberia, flowering in July.

The second species has also a perennial root: the stems two feet high: the flowers in axillary branching aments; appearing towards autumn, but seldom followed by seeds in this climate. It is at first male only, but afterwards has male and female flowers on the same plant. It is a native of Canada and Virginia.

The third is a perennial plant, sending up many stalks from the root, which rise three or four feet high: the leaves are four inches long, and two inches and a half broad, serrate, of a deep green on their upper side, but very white on their under; having five longitudinal veins; they stand upon very long footstalks: the flowers axillary in loose aments, and not succeeded by seeds in this climate. It is a native of the East Indies.

Culture.—These plants may be increased by parting or slipping the roots in the autumn or early in the spring, and planting them out where they are to remain.

The third sort is rather tender, and should have a dry situation where it is warm and sheltered, or be kept in pots to be sheltered under frames, or in the green-house, during the severity of the winter season.

The two first sorts afford variety in the borders and clumps of pleasure grounds, and the last among potted plants.

V A L

VALERIANA, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Triandria Monogynia*, and ranks in the natural order of *Aggregatæ*.

The characters are: that there is scarcely any calyx; a superior margin: the corolla a nectariferous tube on the lower side, gibbous: border five-cleft: segments obtuse: the stamina three,

VOL. II.

V A L

or fewer (in one species four): filaments awl-shaped, erect, length of the corolla: anthers roundish: the pistillum is an inferior germ: style filiform, length of the stamens: stigma thickish: the pericarpium a crust not opening, deciduous, crowned: the seeds solitary, oblong.

The species cultivated are: 1. *V. rubra*, Common or Broad-leaved Red Valerian; 2. *V. angustifolia*, Narrow-leaved Red Valerian; 3. *V.*

3 R.

Calcitrapa, Cut-leaved Valerian: 4. *V. Phu*, Garden Valerian; 5. *V. tripteris*, Three-leaved Valerian; 6. *V. montana*, Mountain Valerian; 7. *V. Celtica*, Celtic Valerian; 8. *V. tuberosa*, Tuberous-rooted Valerian; 9. *V. Pyrenaica*, Pyrenean Valerian; 10. *V. olitoria*, Common Corn-Salad, or Lamb's Lettuce.

The first has woody perennial roots, as thick as a man's finger, spreading very wide: the stems about three feet high, round, smooth, grayish, hollow: at each joint are two (sometimes three) smooth, spear-shaped leaves, near three inches long, and an inch broad; the upper part sends out branches by pairs, which, with the principal stem, are terminated by red flowers growing in corymbs. It is a native of France, Switzerland, Italy, &c. flowering all the summer and autumn.

The second species has the root not so large as in the first sort: the stems two feet high or more, branching on each side from the root to within six inches of the top: the leaves three or four inches long, but as narrow as those of flax: the upper part of the stem naked, and terminated by a compact corymb of bright red flowers, smaller than those of the former. It is a native of the mountains of France, Switzerland, &c.

The third is an annual plant: the lower leaves, which spread on the ground, are cut into many obtuse segments: the stalks, when the plants are in good ground, rise near a foot and half high, but upon dry stony soils not half so high, and when they grow out of the joints of old walls, not more than three inches in height; are hollow, smooth, and round, sending out branches by pairs from the upper joints: the segments of the pinnatifid leaves are very narrow: stem and branches terminated by tufts (corymbs) of flowers shaped like those of the fourth sort, but smaller and tinged with flesh-colour at the top. It is a native of the South of France, &c. flowering early in the spring.

It varies with the lower leaves pinnatifid.

The fourth species has thick roots, fleshy, jointed, spreading near the surface in a very irregular manner, crossing each other, and matting together by their small fibres: many of the root-leaves entire, others divided into three, five, or seven, obtuse lobes, of a pale green and quite smooth: the stems three or four feet high, hollow, sending out lateral branches by pairs: the stem-leaves opposite at each joint, composed of four or five pairs of long narrow leaflets, terminated by an odd one: the stem and branches terminated by corymbs of small white flowers. It is a native of Silesia, Barbary, &c. flowering from May to July, with the odour of the flowers very pleasant.

The fifth has a perennial root, long, unequal, brownish, strong-smelling: the root-leaves oblong-cordate, bluntish, smooth, obtusely serrate-toothed, on long petioles; the two first of these that come out are more inclined to roundish, and are only slightly crenate: the stem upright, undivided, about a foot high: the stem-leaves two or three pairs, smooth, ternate, on short petioles: leaflets confluent at the base, lanceolate, acute, unequally subserrate, the middle one larger than the others; they vary much, being gash-serrate, crenate, or even quite entire; the uppermost are sometimes lanceolate-linear and quite entire, sometimes pinnate with five leaflets: the flowers numerous, white, in loose corymbs. It is a native of the Alps of Switzerland, flowering here from March to May.

The sixth species agrees in stature and habit with the preceding; but this is more tufted, and has the root commonly creeping horizontally, more divided, and not smelling so strongly: all the leaves are acute, unequally serrate or toothed and smooth; the root-leaves are on long petioles, and more or less attenuated at the base towards the petiole: the stem-leaves vary in number, are on short petioles, and rather oblong: the stem is upright, simple, a foot or eighteen inches high: the flowers in a corymb, whitish or purplish. It is a native of Switzerland, Austria, &c. flowering here in June and July.

The seventh species has a perennial root, black, oblique, with long fibres, smelling very strong, aromatic, caulk cent at top and scaly with the remains of the deciduous leaves; it is often in tufts with an upright stem, four or five inches high: all the leaves are quite entire and obtuse; the root-leaves subovate, and attenuated into the petiole at the base; stem-leaves two, opposite, linear and sessile, about the middle of the stem, but there are sometimes none: the stem slender, simple, terminated by a few small whitish flowers in a corymb. It is found in Switzerland, flowering in June.

The eighth species has roots perennial, and tuberous, by which it is easily distinguished. It is a native of the South of Europe, flowering in May and June.

There is a variety with the roots in the form of an olive.

The ninth species has a perennial fibrous root, from which come out many heart-shaped leaves, on petioles more than a foot in length; they are four inches over each way, bluntly serrate, smooth, and of a bright green on their upper surface, but pale and a little hairy underneath: the stalks rise three feet high, are hollow, channelled, and send out opposite branches towards the top: the stem-leaves opposite,

2 Siberian Speedwell

shaped like the lower ones, but a little pointed; and frequently at the top there are ternate leaves standing upon short foot-stalks: the stem and branches are terminated by umbels of pale flesh-coloured flowers, having very short spurs. It flowers in June, and is a native of the Pyrenees.

The tenth has a small annual, fibrous, pale brown root: the stem dichotomous, somewhat spreading, from four inches to a span, and even a foot or more in height (in gardens); round, grooved, or angular, tender, often tinged with purple on one side: the leaves glaucous, pale, obovate-lanceolate or rather linear-tongue-shaped: the bottom leaves many, usually entire, but sometimes very slightly toothed near the base, somewhat spreading, rather succulent, smooth, veiny, and a little wrinkled, from three-quarters of an inch to two inches in length: the stem-leaves opposite at each subdivision, sessile, remote, usually more toothed than the bottom leaves: both these and the stem are ciliate or fringed at the edge with fine white hairs: the flowers are very small, of a pale blueish colour, and collected into a close little corymb, protected by an involucre. It is a native of Europe and Barbary, flowering in April and May. It is used in salads in the early spring and winter, under the name of Corn Salad, or Lamb's Lettuce.

There is a variety, which is smaller, with jagged leaves.

Culture.—The two first sorts may be increased by parting the roots, and planting them out in the autumn or spring season where they are to grow.

They may also be raised from seed sown at the same times, in the situations where the plants are to grow.

The third may likewise be raised from seeds, by sowing them as above, without any trouble.

The fourth may be increased by parting the roots, and planting them out in the autumn on fresh ground where they are to grow.

The fifth may be raised in the same way, being allowed good room as it spreads.

The three following sorts are more difficult to preserve, requiring a stony soil and cold exposure.

The ninth sort may be raised from seeds sown in a moist shady border soon after they are ripe, managing the plants as in the first sort.

The last sort, when cultivated for the purpose of salads, should be sown in the latter end of summer, or beginning of autumn, in an open place where it is to grow; the plants being afterwards thinned out by hoeing, and kept clean from weeds; when they will be fit for use very early in the spring while quite young.

All the sorts except the last may be introduced in the borders for the purpose of variety, and most of them continue many years.

The last is used as an early spring salad herb.

VERATRUM, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Polygamia Monoecia*, and ranks in the natural order of *Coronariæ*.

The characters are: that in the hermaphrodite there is no calyx, unless the corolla be considered as such: the corolla has six petals, oblong, lanceolate, thinner at the edge, serrate, permanent: the stamina have six awl-shaped filaments, pressing the germs, more spreading at the tips, shorter by half than the corolla: anthers quadrangular: the pistillum has three erect germs, oblong, ending in scarcely apparent styles: stigmas simple, patulous: the pericarpium three capsules, oblong, erect, compressed, one-celled, one-valved, gaping inwards: the seeds many, oblong, blunter at one end, compressed, membranaceous, fastened in a double row: male flower on the same plant, below the hermaphrodite—the calyx, corolla, and stamina, as in the hermaphrodite: the pistillum an indistinct, vain rudiment.

The species cultivated are: 1. *V. album*, White-flowered Veratrum, or White Hellebore; 2. *V. nigrum*, Dark-flowered Veratrum; 3. *V. luteum*, Yellow-flowered Veratrum.

The first has a perennial root, composed of many thick fibres gathered into a head: the leaves oblong-ovate, ten inches long, and five broad in the middle, rounded at the end, and having many longitudinal plaits: the stems three or four feet high, branching out on every side almost their whole length: under each of these branches is placed a narrow plaited leaf, and these diminish in size as they are near the top of the stem: the branches and principal stem are terminated by spikes of flowers set very close together, of a greenish white or herbaceous colour; appearing in July. It is a native of Greece.

The second species has a perennial root like the first sort: the leaves are longer and thinner, plaited in like manner, but are of a yellowish green colour, and appear sooner in the spring: the stalks also rise higher: it has fewer leaves, and does not branch out into so many spikes: the flowers are of a dark red colour, with the petals spread open flat; appearing almost a

month sooner. It is a native of Austria and Siberia.

The third has a large tuberous root: the leaves oblong, having several longitudinal furrows, or plaits; they are four or five inches long, and two broad in the middle, and spread themselves on the ground; between these comes out a single stem, near a foot high, having a very few small leaves or sheaths placed on it alternately: the flowers are produced at the top, in a single thick close spike; are small, and of a yellowish white colour, appearing in June. It is a native of North America.

Culture.—These plants may be increased by seed and parting the roots.

The seed should be sown in the autumn or early spring upon a bed or border of light earth, or in a box filled with the same sort of mould. When the plants are come up in the spring keep them clear from weeds, and refreshed with water occasionally when the season is hot and dry; and in the following autumn, when the leaves decay, take them up carefully without injuring the roots, and plant them out about half a foot square in a fresh bed of light mould; and when they have remained in it till fit for flowering, they should be removed into the borders, clumps, or other parts. This is however a tedious method, as they seldom flower in less than four years; therefore the root method is mostly had recourse to.

The roots may be divided in autumn when the leaves decay, and be planted out in a light fresh rich mould where they are to grow; they should not be removed oftener than once in about four years. The roots should not be parted too small.

These plants have a fine effect in the middle of large borders, clumps, and other similar situations.

VERBASCUM, a genus furnishing plants of the hardy annual, biennial, and perennial kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Luridæ*.

The characters are: that the calyx is a one-leaved perianth, five-parted, small, permanent: segments erect, acute: the corolla one-petalled, wheel-shaped, a little unequal: tube cylindric, very short: border spreading, five-parted: segments ovate, obtuse: the stamina have five filaments, awl-shaped, shorter than the corolla: anthers roundish, compressed, erect: the pistillum is a roundish germ: style filiform, length of the stamens, inclined: stigma thickish, obtuse: the pericarpium is a roundish capsule, two-celled, two-valved, opening at top: receptacles half ovate, fastened to the partition: the seeds numerous, angular.

The species cultivated are: 1. *V. Boerhaavii*, Annual Mullein; 2. *V. Blattaria*, Moth Mullein; 3. *V. Thapsus*, Great Mullein; 4. *V. phlomoides*, Woolly Mullein; 5. *V. Lychnitis*, White Mullein; 6. *V. sinuatum*, Scollop-leaved Mullein; 7. *V. ferrugineum*, Rusty Mullein; 8. *V. Phoeniceum*, Purple Mullein; 9. *V. Myconi*, Borage-leaved Mullein.

The first has an annual root: the stem from three to four feet high: the leaves sessile but not decurrent, spatulate, narrower at the base, sinuate but scarcely lyrate, almost naked above, somewhat tomentose beneath: the spike loose, terminating, with the flowers sessile, not crowded very much together, but several to each bracte: the corollas are yellow, with the stamens and pistils purple: the flowers have an agreeable scent at a little distance; but if smelt to long, or too near, it becomes less pleasant; they appear in June and July. It is a native of the South of Europe.

The second species has an annual fusiform root: the stem about three feet high, erect, branched, leafy, angular, smooth: the leaves obovate-oblong, doubly-serrate, smooth, embracing: root-leaves sublyrate: the racemes terminating, glandular-hairy, stiff, many-flowered: the flowers peduncled, solitary, yellow streaked more or less with purple, having each a single ovate bracte at the base of the peduncle. It is a native of the South of Europe, Germany, Switzerland, &c.; and is very ornamental, flowering from July to November, or even later in mild weather.

The third has a biennial root, spindle-shaped: the stem erect, simple, stiff, and straight, from three to five feet high, leafy, woolly, angular, winged: the leaves alternate, decurrent, oblong, nearly entire, very thickly clothed on both sides with white branched intricate villose hairs: the spike terminating, erect, cylindrical, many-flowered: the flowers sessile, closely set, bright yellow, sometimes but rarely white. It is a native of Europe and Siberia, flowering in July and August.

The fourth species has a biennial root: the stem erect, spiked, very tomentose: the leaves ovate, not at all cordate, crenate; the lower ones on a petiole which is flat above; the upper ones sessile, half embracing but not decurrent: the raceme spike-shaped, with scattered lanceolate bractes; within each of which are four flowers, the middle ones blowing first, then the lowest, and lastly the two lateral ones. It is a native of Italy, Germany, and the South of France; flowering in June and July.

The fifth has a biennial root: the stem erect, seldom more than three feet high, stiff and

straight, angular, woolly, leafy, terminating in a panicle very much branched: the leaves elliptic-oblong, somewhat wedge-shaped, crenate, closely woolly beneath, but nearly smooth on the upper-side, netted-veined; the radical ones attenuated at the base: the stem-leaves ovate, sessile, but not decurrent: the branches of the panicle racemed, many-flowered: the flowers pedicelled, in bundles, cream-coloured with yellow filaments and saffron-coloured anthers. It is remarkable for its straight wand-like angular stem and cream-coloured flowers, which are produced in great numbers in a compound clustered terminating raceme. It is a native of Europe.

The sixth species has a biennial root: the radical leaves repand, or obtusely sinuate-pinnatifid: stem-leaves oblong, waved, decurrent a little at the base on each side: branch leaves ovate or cordate, a little decurrent; the first of these are opposite, the rest alternate: the flowers sessile, glomerate, in an interrupted spike. It is a native of the South of France, Italy and Barbary; flowering in July and August.

The seventh has a perennial root: the bottom leaves are ovate-oblong, indistinctly crenate, (doubly crenate,) dark green above, pale green beneath, standing upon pretty long footstalks: the stalk rises three or four feet high, branching out on each side, and has a few sharp-pointed small leaves on the lower part, sitting close to the stalk: the flowers are disposed in a long loose spike on the upper part of the stalk; they come out upon short slender pedicels, three or four from the lower joints; above these there are two at each joint, and at the top they are single; they are of a rusty iron colour, and larger than those of the common sort; they appear in July and August. It is a native of the South of Europe.

The eighth species has also a biennial root: the radical leaves ovate, subsessile, naked, even, wrinkled, scarcely crenate: the stem erect, simple, two feet high: the branches from the lowest axils, erect, simple, length of the stem, all angular, subpubescent with hairs clammy at the tip: the stem leaves cordate, sessile, smooth, wrinkled and veined: the raceme of all terminating, simple, a foot long: the peduncles simple, solitary, one-flowered. It is a native of the South of Europe.

The ninth has a perennial root, composed of slender fibres: the leaves, which spread flat on the ground, are of a thick fleshy substance, of an ovate shape, indented on their edges, woolly, and of a dark green colour; they are sessile or subsessile, embrace the crown of the root, and lie over each other; they continue in verdure all the year, but in winter change to a much darker

green: from among these leaves arise several scapes or naked slender stalks, about four inches high, which divide into three or four pedicels at the top, hairy and of a brown-purplish colour, each sustaining one large flower, of a fine blue, so deeply divided as to appear to be five-petalled: the segments are oval, obtuse, and spread open flat, like the Auricula: the flowers are large in proportion to the size of the plant, of a blueish purple colour, and highly ornamental, appearing in May, and continue successively in blossom for several months. It is a desirable plant to cultivate, especially for decorating rock-work. It is a native of the Pyrenees.

Culture.—These plants may all be increased by seeds, and offsets taken from the roots.

The well ripened seeds should be sown in the autumn or early spring in a bed of light mould, or in the borders or other parts where they are to remain, covering them lightly in. When the plants are up a few inches in height, in the bed method, they should be removed into nursery-rows till the autumn, when they must be removed to where they are to remain.

The annual sort is however best sown at once where the plants are to grow, which is best done in patches.

The offsets of all the perennial sorts should be taken off in the autumn, or very early in the spring, and be planted out where they are to grow. This is better than afterwards transplanting them.

They are all hardy plants, that succeed in almost any soil.

They afford a good effect in their different foliage, and sweet scent of their flowers, in the large borders, clumps, and other parts of pleasure grounds; the larger sorts being placed backwards in them.

VERBENA, a genus containing plants of the hardy herbaceous and tender exotic kinds.

It belongs to the class and order *Diandria Monogynia*, (*Didynamia Gymnospermia*), and ranks in the natural order of *Personatæ*.

The characters are: that the calyx is a one-leaved perianth, angular, tubular, linear, five-toothed, the fifth toothlet truncate, permanent: the corolla is one-petalled, unequal: tube cylindrical, straight for the length of the calyx, then widening and curved in: border spreading, half five-cleft: segments rounded, almost equal: the stamina have two or four filaments, bristle-shaped, very short, lying within the tube of the corolla; two of them shorter (when there are four:) anthers curved in, as many as there are filaments: the pistillum is a four-cornered germ: style simple, filiform, length of the tube: stigma obtuse: the pericarpium is very slender, and scarcely manifest, or almost none: calyx con-

taining the seeds: the seeds two or four, oblong.

The species cultivated are: 1. *V. Indica*, Indian Vervain; 2. *V. supina*, Trailing Vervain; 3. *V. orubica*, Betony-leaved Vervain; 4. *V. Jamaicensis*, Jamaica Vervain; 5. *V. Mexicana*, Mexican Vervain; 6. *V. globiflora*, Globe-flowered Vervain; 7. *V. bonariensis*, Cluster-flowered Vervain; 8. *V. hastata*, Halberd-leaved Vervain; 9. *V. triphylla*, Three-leaved Vervain.

There are many other species that may be cultivated for variety.

The first is an annual plant, very much resembling the fourth sort, but easily distinguished from it by the stem and branches being smooth, except the base of the leaves and the part of the branches between the leaves, which are ciliate: the leaves also are much narrower, being truly lanceolate and drawn to a point at both ends: the spike is the same, but the colour of the corolla is purple. It is a native of Ceylon, flowering in August.

The second species has a biennial root (annual): the stalks near two feet high, branching out greatly: the leaves sessile: the flowers disposed in long loose spikes singly at the end of the branches; they are of a light blue colour, and large. It flowers in July and August, and is a native of Spain, Portugal and Algiers.

The third arises with a shrubby stalk near three feet high, divided into three or four branches: the leaves oblong-ovate, placed by pairs, deeply serrate, deep green above, but hoary beneath; their footstalks are short, and have leafy borders running from the base of the leaves: the flowers grow in thick terminating spikes about a foot in length; are large, of a fine blue colour, and have small acute-pointed leaves intermixed with them; they come out in June and July. It is biennial, and a native of South America.

The fourth species has the stem three or four feet high, very much branched and diffused, and being suffrutescent at the base it seems to be more than annual: the stem and branches rough with hair: the leaves opposite, ovate, obtuse or acute, serrate, gradually and for a considerable length attenuated at the base: from the axil between two opposite branches comes forth a fleshy spike, a foot long, unequally cylindrical, stiff and green: the flowers blow in succession, beginning at the bottom, very few together, violet-coloured, with the throat and long slender incurved tube white. It is a native of Jamaica, Barbadoes, &c.

The fifth has a shrubby stalk, which rises five or six feet high, and divides into several branches: the leaves sessile, oblong, serrate, ending in acute points, two inches long, one

inch broad near the base, of a light green colour on both sides: the branches are terminated by slender loose spikes of small pale flowers, the calyxes of which afterwards become swelled and almost globular; are reflexed, and set with stinging hairs. It is a native of Mexico, flowering in July and August.

The sixth species is a fragrant shrub: the stem erect, branched, ash-coloured, the height of a man: the branches erect, round, like the stem: the branchlets rugged, pithy, bay-coloured: the shoots villose, rugged, from four-cornered round, green at top: the leaves opposite, seldom three together, spreading, sharp at both ends, crenate or bluntly serrate, except at the base, where they are entire, attenuated into the petiole, marked with lines above, and with erect, alternate, prominent nerves beneath, very much veined, wrinkled, villose, rugged, reclining, permanent, fragrant: petioles shorter than the leaf, round on one side, grooved or flat on the other, villose, edged with the decurrent leaf: heads terminating, axillary, peduncled, roundish, bracted, imbricate: the peduncles erect, single or two from each axil, scarcely longer than half the leaf, villose, rugged: the flowers sessile, one to each bracte, very close, compressed, white. It is a native of South America.

The seventh has four-cornered stalks which rise to the height of five or six feet, sending out side branches by pairs: the leaves three inches long, and about three quarters of an inch broad, of a pale green colour, and serrate: the spikes terminating, clustered, the longest about two inches, the others about half as long: the flowers blue, appearing late in summer. It is a native of Buenos Ayres.

The eighth species sends up many four-cornered furrowed stalks from the root, which rise five or six feet high: the leaves opposite, oblong, about three inches long, and an inch broad near the base, ending in acute points, deeply serrate on slender petioles: from the same joints come out short branches, set with smaller leaves of the same form: the stalks are terminated by spikes of blue flowers in clusters, which appear in August. It is a native of Canada.

The ninth is a very sweet-smelling under-shrub: the stem upright, branched, round, ash-coloured, a fathom in height: the branches three or four in a whorl, spreading very much, rugged: the branchlets six-cornered, bay-coloured: the leaves generally three together, sometimes four, spreading, of a bright green colour, and very pleasant smell like that of the lemon: the flowers in an erect terminating panicle, composed of spikes.

Culture.—These plants are not raised without

difficulty and attention. They may be increased by seeds, which should be sown in pots, or on a hot-bed, in the early spring, plunging the pots in the bed. When they are in a state of growth to remove, they should be planted in separate pots and replunged in a fresh hot-bed, shade being given till they have taken new root, when they must have the management of tender plants of the exotic kind. The annual sorts should be kept in the stove, or a glass case, where there is a bark-bed to plunge them in when too large to be continued under the frames; and the perennial sorts may be placed simply in such cases, air being admitted in a cautious manner.

Of these kinds, such as do not afford good seeds in this climate, may be increased by planting cuttings in the summer months in pots of good mould, placing them in the bark-bed of the stove, where they may be preserved many years.

The eighth sort may be raised from seeds by sowing them in the autumn, and by parting the roots and planting them out at the same time. They succeed best on a soft loamy soil, and are so hardy as to thrive in the open air.

The ninth sort may be readily increased by planting cuttings in the spring or autumn in pots of good mould. It should have the protection of the green-house or a glass case.

They afford variety among other potted plants in the green-house and stove, and some of the hardy sorts occasionally in the open ground.

VERBESINA, a genus affording plants of the herbaceous and woody flowering exotic kinds.

It belongs to the class and order *Syngenesia Polygamia Superflua*, and ranks in the natural order of *Compositæ Oppositifoliæ*.

The characters of which are: that the calyx is common concave: leaflets oblong, channelled-concave, erect, commonly equal, in a double row: the corolla compound radiate: corollets hermaphrodite, many, in the disk: females about five in the ray: proper of the hermaphrodite funnel-form, five-toothed, erect:—female ligulate, trifid and wide or simple and very narrow: the stamina in the hermaphrodites: filaments five, capillary, very short: anthers cylindrical, tubular:—the pistillum of the hermaphrodite: germ somewhat oblong: style filiform, length of the stamens: stigmas two, reflexed:—in the females, germ somewhat oblong: style filiform, length of the hermaphrodite: stigmas two, reflexed: there is no pericarpium: calyx unchanged: the seeds in the hermaphrodites solitary, thickish, angular: pappus of two awl-shaped unequal awns: in the females very like the others: the receptacle chaffy.

The species cultivated are: 1. *V. alata*, Wing-stalked Verbesina; 2. *V. Chinensis*, Chinese

Verbesina; 3. *V. nodiflora*, Sessile-flowered Verbesina; 4. *V. fruticosa*, Shrubby Verbesina; 5. *V. gigantea*, Tree Verbesina.

The first is an herbaceous plant, with an upright stem about two feet high, subdivided, round, winged, rough-haired: the branches alternate, erect, axillary: the leaves oblong, acuminate, angular-toothed, nerved, somewhat rugged, rough-haired: the stem has four wings formed by the leaves running down it: the peduncles elongated, terminating, pubescent, with flowers in single heads, of a deep orange-colour. It is perennial, and a native of South America, flowering most part of the summer.

The second species is a shrub with a single, round, submentose stem and undivided branches from the upper axils of the leaves; which are somewhat tomentose, bluntish, petioled: the flowers terminating, solitary, peduncled, and yellow.

The third has an annual root: the stem herbaceous, branched, a foot high, round, even: the leaves sessile, mostly terminating, cuneate-ovate, acuminate, nerved, hispid: the flowers sessile in the axils of the terminating leaves, two or three together, yellow, appearing in July. It is a native of the West Indies.

The fourth species rises with a shrubby stalk seven or eight feet high: the leaves deeply serrate and cut somewhat like those of the evergreen oak: the flowers are yellow, produced from the side of the stalks, and appear in July. It is a native of the West Indies.

The fifth has the stem fifteen feet high, and the thickness of a thumb at the lower part, smooth, green, and viscid; it is filled without interruption by a white inodorous pith, as in a rush; is simple, or at least but very slightly divided at top: and the whole stem is aphyllous, the leaves occupying only the upper part and branchlets: they are alternate, foot-stalked, and the largest are about a foot and a half long; they are villose and pinnatifid, with distant oblong lobes: from the bosoms of the upper leaves spring round whitish-villose peduncles, bearing at their tips the flowers, which are slightly foot-stalked, and closely heaped together, forming a kind of panicle: the corollets are white, and the anthers black. It is a native of the West Indies.

Culture.—These plants may be increased by sowing the seeds upon a moderate hot-bed, or in pots plunged into it, in the early spring months, and when the plants are of sufficient growth they should be removed into separate pots, or into a new hot-bed, giving shade till they become new-rooted; afterwards managing them as tender annual plants, being careful not to draw them up weak: about the middle of sum-

mer they may be taken up with balls to their roots, and be planted in a warm sheltered border, being protected and watered till re-rooted, little care being afterwards necessary: these produce seeds often in the autumn; but in the stove they may frequently be preserved over the winter.

They produce variety in stove- and greenhouse collections, and sometimes in the borders during the summer season.

VERONICA, a genus comprising plants of the herbaceous perennial and shrubby kinds.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Personateæ*.

The characters are: that the calyx is a four-parted perianth, permanent: segments lanceolate, acute: the corolla one-petalled, wheel-shaped: tube length almost of the calyx: border four-parted, flat, with ovate segments; the lowest narrower, the segment opposite to this wider: the stamens have two filaments, narrower at bottom, ascending: anthers oblong: the pistillum is a compressed germ: style filiform, length of the stamens, declined: stigma simple: the pericarpium is an obcordate capsule, compressed at the top, two-celled, four-valved: the seeds numerous, roundish.

The species cultivated are: 1. *V. Sibirica*, Siberian Speedwell; 2. *V. Virginica*, Virginian Speedwell; 3. *V. spuria*, Bastard Speedwell; 4. *V. maritima*, Sea Speedwell; 5. *V. longifolia*, Long-leaved Speedwell; 6. *V. hybrida*, Welsh Speedwell; 7. *V. incisa*, Cut-leaved Speedwell; 8. *V. decussata*, Cross-leaved Speedwell.

The first has a perennial root: the stem four feet high, rough-haired: the leaves six or seven in whorls, twice as wide as those of the second sort: peduncles terminating solitary; the lateral ones with two opposite oval leaflets: the calyxes five-cleft: the corollets blue, with an oblong tube, and small acute border: the stamens and pistil twice as long as the corolla. It is a native of Siberia, flowering in July and August.

The second species has the stems erect, four or five feet high, having four or five lanceolate leaves in whorls at each joint, serrate, and ending in acute points: the stems are terminated by long slender spikes of white flowers, which appear late in July. It is a native of Virginia and Japan.

It varies with blush-coloured flowers.

The third has a perennial root, sending out many offsets: the lower leaves two inches long, and half an inch broad, pale green and hairy: the stems a foot high, with very narrow lanceolate leaves, placed opposite, and having a few slight serratures on their edges: the stems terminated by long spikes of blue flowers, which

appear in June and July. It is a native of Siberia and Germany.

There is a variety of this also with a flesh-coloured flower.

The fourth species has the stalks not so long as those of the preceding: the leaves by fours and threes round the stalk, on longer footstalks; they are broader at the base, run out into long acute points, are unequally serrate, and of a bright green colour: the flowers are of a bright blue, and appear in July. It is a native of the sea-coasts of Europe.

There are varieties with leaves opposite, in threes or in fours, with blue, blueish, flesh-coloured, and with white flowers.

The fifth has the lower leaves two inches long, and an inch broad in the middle, drawing to a point at each end, serrate, and of a lucid green colour: the stems a foot and a half high, with leaves of the same shape but smaller, and placed opposite; they are terminated by long spikes of blue flowers, which appear in June. It is a native of Germany, Austria, and Russia.

The sixth species has the stems very white and woolly, about a foot high: the leaves oblong, hoary, two inches and a half long, three quarters of an inch broad, sessile: the flowers deep blue in terminating spikes, and from the upper axils: they appear in June and July. It is a native of Russia, Ukrain Tartary, &c.

There is a variety with white flowers.

The seventh has the spikes aggregate, the flowers large, the leaves an inch long, lanceolate wedge-shaped at the base, with lanceolate segments. It is a native of Siberia, flowering in July and August.

The eighth species is a bushy shrub about two feet high: stem upright, round, very much branched: the branchlets alternate, spreading, round or indistinctly quadrangular, closely leaved on every side, having a pubescent line on each side running down from the oppositions of the leaves, which spread very much, are scarce an inch long, acute, coriaceous, smooth and even, one-nerved, paler underneath, evergreen, border cartilaginous, on very short concave smooth petioles, gibbous at the base on the outside: the racemes single, short, few-flowered, towards the end of the branches, not terminating, but just below the top: the pedicels alternate, short, quadrangular, one-flowered. The regular growth of the leaves, decussated or crosswise, distinguishes this species immediately.

Culture.—These plants may be raised by seed and parting the roots.

In the annual sorts the seeds should be sown in the autumn or very early spring, in the borders or places where the plants are to grow, be-

ing lightly covered in : if the seeds be permitted to scatter, good plants may be raised : sometimes they are sown on beds to be afterwards removed.

In the perennial sorts the roots may be parted in the autumn or early spring, and planted out where they are to grow, or in nursery-rows to be afterwards removed.

They should not be parted too small, or oftener than every two years : the large-growing sorts are proper for the borders, clumps, &c. and the trailing kinds for banks and shady slopes, or other similar places : they are hardy, and require only to be kept clean afterwards.

The eighth sort is readily increased by cuttings in the spring and summer, being managed as a hardy greenhouse plant in the same way as the Myrtle.

In very mild winters it sometimes stands secure in the open air.

The annual and perennial sorts afford variety in the borders, clumps, and other parts of pleasure-grounds, and the last among plants of the hardy potted green-house kinds.

VERMIN, a term applied to various small animals that are injurious to garden crops.

Rats and Mice are of this kind, and do much mischief in sheds and other places, where they frequently destroy beans, pease, and other seeds : they should therefore be extirpated as much as possible.

And there are different modes of destroying them ; as by traps, poison, &c. But Mr. Forsyth advises never to use arsenic, or corrosive sublimate, for that purpose, except under particular circumstances, as they are deadly poison : nux vomica will, he thinks, generally answer the end as well, without the danger. He has suggested it as a very good plan to prevent accidents, to "enclose the traps in cases, having holes in the ends of them large enough to admit rats, but small enough to exclude dogs, cats, &c."

The following is recommended as a bait for rat-traps. "Take a pound of good flour, three ounces of treacle, and six drops of the oil of caraways : put them all in a dish, and rub them well together till they are properly mixed ; then add a pound of crumb of bread. The traps baited with this mixture should be set as near their haunts as possible ; but, for two or three days, so as not to fall or strike on the rats going in, but letting them have free liberty to go in and out at pleasure, as this makes them fearless. Some of the bait should also be laid at the rat-holes, and a little of it scattered quite up to the traps, and so on to the bridge of each trap, where a handful may be placed." It may also, he says, "be proper to scent the traps with the

VOL. II.

following mixture, for the purpose of enticing the rats into them.

"Take twenty drops of oil of rhodium, six or seven grains of musk, and half an ounce of oil of aniseed ; put them in a small phial, and shake it well before using ; then dip a bit of twisted paper, or rag, in the mixture, and rub each end of the trap with it, if a box-trap, and put two or three drops on the bridge, leaving the paper or rag in the trap. Of whatever kind the trap is, it should, he says, be scented ; but once in a twelvemonth will be sufficient. Then throw some chaff mixed with a little wheat about the bottom of the trap, in order to deceive the rats ; for they are very sagacious, and will not enter a suspicious place. This will be necessary to be done only at the first time of setting the traps, for after some rats have been caught and have watered and dunged in them, rats will enter boldly when they find others have been there before them : do not, therefore, wash or clean out the trap, as some people do before they set it again, but let the dung and urine remain in it. Keep the places where the traps are set as private as possible ; and when they are set for catching, mix no bread with the bait, as the rats will in that case be apt to carry it away."

It is advised, "when the holes are found quiet, and that no rats use them, to stop them up with the following composition. Take a pint of common tar, half an ounce of pearl-ashes, an ounce of oil of vitriol, and a good handful of common salt, mix them all well together, in an old pan or pot. Take some pieces of paper, and lay some of the above mixture very thick on them ; then stop the holes well up with them, and build up the mouth of the holes with brick or stone, and mortar ; if this be properly done, rats will, he asserts, no more approach these, while either smell or taste remains in the composition."

In order to destroy the rats in places where traps cannot be set, he recommends us to "take a quart of the above bait, then rasp into it three nuts of nux vomica, and add a quarter of a pound of crumb of bread, if there was none before ; mix them all well together, and lay it into the mouth of their holes, and in different places where they frequent ; but first give them of the bait without the nux vomica, for three or four succeeding nights ; and when they find it agrees with them, they will eat that mixed with the nut with greediness."

It is observed that "rats are frequently very troublesome in sewers and drains. In such cases arsenic may be used with success, as follows : Take some dead rats, and having put some white arsenic, finely powdered, into an old pep-

per-box, shake a quantity of it on the foreparts of the dead rats, and put them down the holes, or avenues, by the sides of the sewers at which they come in; this puts a stop to the live ones coming any further; for when they perceive the arsenic, they will, he says, retire immediately; whereas if they were put down without the arsenic the live ones would eat them."

We have, however, found that these animals take arsenic best when it is prepared by being finely levigated and mixed up with very strong old cheese and oatmeal. In order to destroy mice, Mr. Forsyth advises to "take a quart of the bait for rats before there is any bread mixed with it; then take four nuts of nux vomica, and rasp them very fine, otherwise the mice will pick out the food from it, on account of its bitter taste; rub them well together; lay some of it on a piece of paper, or, if without doors, on a piece of tile, removing all other food from the place, and it will kill all that eat of it. What is not eaten should be taken away in the morning, and replaced at night. If this be in a garden, shelter it with boards or tiles, that it may not get wet.

"Open traps should likewise be set, as mice are shy in entering close ones. And care should be taken not to convey these animals into gardens by the straw litter, or other similar materials."

Slugs are a sort of animals that are frequently found harbouring about the foundations of walls, and about the roots of pease, lettuce, &c. "They may," Mr. Forsyth says, "be picked off, and killed, by putting them into a pot in which is a little fine unslaked lime; or the ground where they are should be well watered with soap-suds and urine, mixed with tobacco-water. When they are numerous on the surface of the ground, which frequently happens after rain, or in a dewy morning, fine unslaked lime thrown over the borders, &c., will, he says, destroy them. But he prefers the above mixture, which, if the ground be well watered with it, will bring them up out of their holes, when they very soon die; it will also destroy their eggs, which they always deposit in the earth."

"Snails also, during the winter," he says, "gather themselves together in clusters; and in that season are frequently found in great numbers behind wall-trees, and in holes of the walls. They should be carefully picked off and crushed, which is the only effectual way of getting rid of them. If any should escape, they should be destroyed as they make their appearance in the spring. As they also deposit their eggs in the ground, the borders should be well watered in the above manner."

Wasps and flies are highly destructive of all sorts of fruit: therefore, as soon as the wasp and

large flesh-fly make their appearance, "get ready several bottles or phials; then mix up grounds of wine or beer, with sweepings of sugar, honey, or grounds of treacle, and with this mixture fill the bottles half or three-quarters full, then place some of them at the bottom of the wall, and hang a sufficient number up by a piece of yellow willow, or packthread, on the nails against the walls in different places, observing to empty them frequently, as they fill with flies and wasps; first pour the liquor into an empty bottle, and then shake out the dead insects, crushing them with your foot, that none of them may revive; then pour back the liquor into the bottles and phials as at first. In this manner a great many may be destroyed, he says, before the fruit becomes ripe. If you begin to hang up the bottles as soon as you see the fly, which comes much earlier than the wasp, you will be able to destroy great numbers of them, and will have the bottles ready for the wasps when they make their appearance. The fly will be found as destructive as the wasp to grapes." And "when the weather is hot, and the wasps are numerous, if they do not enter the bottles fast enough, (which will happen when the fruit is very ripe), a little oil may, he says, be put in a cup, and with a feather dipped in it touch their backs and they will instantly drop down; when you will find them turned black and green by the effects of the oil."

Birds attack fruit much when it begins to ripen. The best preventive in this case is, Mr. Forsyth says, "to cover the trees with nets, or bunting, a sort of cloth of which ships' colours are made." See *VIRIS*.

There are many other animals of the insect tribe that are likewise highly destructive to fruits and garden crops, but which are noticed under the articles which they are found to injure.

VERVAIN. See *VERBENA*.

VERVAIN MALLOW. See *MALVA* and *URENA*.

VIBURNUM, a genus containing plants of the deciduous and evergreen flowering kind.

It belongs to the class and order *Pentandria Trigynia*, and ranks in the natural order of *Dumoseæ*.

The characters are: that the calyx is a five-parted perianth, superior, very small, permanent: the corolla one-petalled, bell-shaped, five-cleft: segments blunt, reflexed: the stamina have five awl-shaped filaments, length of the corolla: anthers roundish: the pistillum is an inferior germ, roundish: style none, but in its stead a turbinate gland: stigmas three: the pericarpium is a roundish berry, one-celled: the seeds bony, roundish.

The species cultivated are: 1. *V. Lantana*, Wayfaring Tree; 2. *V. Opulus*, Water Elder; 3. *V. Lentago*, Pear-leaved Viburnum; 4. *V. Cassinoides*, Thick-leaved Viburnum; 5. *V. nitidum*, Shining-leaved Viburnum; 6. *V. lavi-gatum*, Cassioberry Bush; 7. *V. nudum*, Oval-leaved Viburnum; 8. *V. prunifolium*, Plum-leaved Viburnum; 9. *V. dentatum*, Tooth-leaved Viburnum; 10. *V. Thunbergii*, Laurustinus or Laurustine.

The first is a thickly-branched shrub or small tree, having round, plant, mealy twigs, with the same kind of tufted stellated pubescence as is found on the flower-stalks, backs, and even upper surfaces of the leaves: the leaves opposite, somewhat elliptical, cordate, obtuse, serrate, strongly veined, turning dark red before they fall in autumn: stipules none: the flowers whitish, in large terminating, solitary, many-flowered cymes. It is a native of most parts of Europe, flowering here in May. It is sometimes known by the name of Plant Mealy Tree; and according to Withering the bark of the root is used to make Birdlime.

There is a variety in North America with larger leaves, of a bright green; and with variegated leaves in nurseries.

The second species is a small bushy tree, smooth in all its parts, and very much branched: branches opposite, round: the leaves subcordate, with three great unequally serrate lobes, veined, paler beneath; their petioles bearing several cup-like glands towards the top, and a pair or two of erect linear appendages, scarcely to be called stipules, near the base: the cymes terminating, solitary, composed of many white flowers, radiant: the inner perfect, small, resembling those of Elder; those in the margin abortive, consisting merely of a large irregular flat petal without any organs of fructification: the stigmas nearly sessile, close together: the berries drooping, globular, crowned with five very small scales of the calyx, red, very succulent. It is a native of Europe, flowering early in June; the bright-red berries ripen about September, and towards the middle of October the leaves assume a beautiful pink colour.

There is an American variety, which is a shrub, that has the twigs of a shining red colour, and which rises eight or ten feet high, with many side branches, covered with a smooth purple bark: the leaves cordate-ovate, ending in acute points, deeply serrate, having many strong veins, and standing upon very long slender footstalks.

There is another beautiful variety common in plantations under the name of Guelder Rose, bearing large round bunches of abortive flowers only, which rises to the height of eighteen or

twenty feet if permitted to stand: the stem becomes large; the branches grow irregular, and are covered with a gray bark: the leaves are divided into three or four lobes, somewhat like those of the Maple; they are about three inches long, and two and a half broad, jagged on their edges, and of a light green colour: the flowers come out in a large corymb, are very white, and, being all neuters, are barren; from their extreme whiteness, and swelling out into a globular form, some country people have given this shrub the name of Snow-ball Tree. It is also sometimes called Elder Rose and Rose Elder.

The third has the branches bent or hanging down: the petioles waving on the edge: the leaves thick, like those of the tenth sort, smooth, serrulate with very small teeth: the germ terminating, awl-shaped, ventricose at the base. It is a native of North America, flowering here in July.

The fourth species has the lowest leaves ob-ovate; the next ovate; the upper ones lanceolate. It is a native of North America. It flowers in June.

The fifth is a native of North America. It flowers in May and June.

The sixth species has the leaves petioled, broad-lanceolate, sharpish, without any raised veins: the petioles decurrent along the back, whence the twigs are acipital: the corymb short: the stem twelve or fourteen feet high, sending out branches from the bottom to the top: the leaves about an inch long, and more than half an inch broad, of a light green colour, opposite, on short footstalks: the peduncles axillary, very short, supporting small umbels of white flowers, which appear in July. It is a native of South Carolina.

The seventh has a strong stem, covered with a brown smooth bark, and rising to the height of ten or twelve feet, sending out woody branches on every side the whole length, which have a smooth purplish bark: the leaves opposite, five inches long and two and a half broad, smooth and of a lucid green above, veined and of a light green beneath, entire at the edges, (indistinctly notched,) and rounded at both ends; of the same thickness with those of the Broad-leaved Laurustinus: the flowers are produced in large umbels (cymes) at the end of the branches, are in shape and colour like those of the common Laurustinus, but smaller; and the stamens are much larger than the corolla: they appear in July, and are succeeded by roundish berries, which, when ripe, are black. It is a native of America, flowering in May and June.

There are varieties with deciduous and ever-green leaves.

The eighth species rises with a woody stalk ten or twelve feet high, covered with a brown bark, and branching its whole length: the branches, when young, are covered with a smooth purple bark: the leaves two inches long, and an inch and quarter broad, slightly serrate, and on short slender footstalks, opposite or without order: the flowers in small umbels (cymes) lateral and terminating; these are white, and smaller than in the first sort, appearing in June, and are sometimes succeeded by berries. It grows naturally in most parts of North America, where it is commonly called *Black Haw*.

The ninth has the stalks soft and pithy, branching out greatly from the bottom upward, and covered with a gray bark: the leaves three inches long, and nearly as broad, strongly veined, of a light green colour, placed opposite upon pretty long footstalks: the flowers in terminating corymbs, white, and almost as long as those of the first sort, appearing in June. It is a native of North America.

There are varieties with the leaves smooth on both sides, and with the leaves downy underneath and drawn out to a point.

In the tenth species the leaves are seldom more than two inches and a half long, and an inch and quarter broad; they are rounded at their base, but end in acute points, are veined and hairy on their under side, and not of so lucid a green colour as the following sort on their upper.

There are several varieties; as the smaller hairy leaved, in which the umbels (cymes) of flowers are smaller, and appear in autumn, continuing all the winter. The plants are much hardier.

The shining-leaved, in which the stalks rise higher, and the branches are much stronger: the bark is smoother, and turns of a purplish colour: the leaves are larger, of a thicker consistence, and of a lucid green colour: the umbels (cymes) are much larger, and so are the flowers; these seldom appear till the spring, and when the winters are sharp, the flowers are killed, and never open unless they are sheltered.

There is a sub-variety of this with variegated leaves; with gold-and silver-striped; in which the branches are warted, the younger ones four-cornered: the leaves opposite, ovate, on short petioles, rigid, shining, perennial; the younger ones hirsute, with short ferruginous villose hairs: flowers in crowded cymes, with little bractes between them: the corolla white; and the berries, when ripe, blue.

The common, with narrower leaves, hairy only on the edge and veins underneath: the fruit smaller.

And the Upright *Laurustinus*.

Culture.—These plants may some of them

be increased by seeds, most of them by layers, many by cuttings, and a few by suckers.

The seeds in the deciduous kinds should be sown in the autumn or spring in beds of light fine mould, being well covered in. The plants appear in the first or second year, and when they are of a twelvemonth's growth they should be planted out in nursery-rows, to be continued till of proper growth to plant out in the shrubberies or other parts of pleasure-grounds, as from two to five feet.

In the *Laurustinus* kinds, the seeds after being mixed with mould in the autumn soon after they become ripe, and exposed to the air and rain in the winter, should in the spring be sown on a gentle hot-bed, or in pots plunged into it; the plants being continued in the bed till the autumn, when they should be removed and managed as in the layer method. The plants raised in this way are said to be hardier than those raised from layers.

The first sort is tedious in being raised from seeds.

In the layer, which is the most expeditious mode of raising most of these plants, the young lower branches should be laid down in the autumn or spring, being pegged down in the usual manner in the earth, when they mostly become well rooted in a twelvemonth, and may then be taken off and planted out where they are to remain, or in the nursery; and sometimes, in some of the kinds, a few are put in pots.

The best season for removing the tenth sort is in the early autumn, that they may be well rooted before the winter.

The first sort succeeds best by layers put down in the autumn. And the striped variety may be increased by budding it upon the plain sort.

The cuttings may be made in the autumn from the strong young shoots, being planted in a moist border in rows, when in the following summer many of them will be well rooted, and form little plants. Most of the deciduous sorts may be raised in this way.

The suckers should be taken up in the autumn or spring with root-fibres, and be planted out in nursery-rows to have a proper growth. The *Guelder Rose* may be readily increased in this way, and sometimes the *Laurustinus*.

The fourth sort is rather tender in winter while in its young growth, as well as the sixth, and should have protection in that season. A plant or two should be constantly laid in pots under shelter. This last is easily increased by layers.

These plants afford much variety and effect in shrubbery and other parts of pleasure-ground, when planted out in a mixed order. The ever-

green sort are often used to cover disagreeable objects. The flowering evergreens are likewise often set out in pots.

VICIA, a genus furnishing plants of the biennial; perennial, and annual hardy kinds.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved perianth, tubular, erect, half-five-cleft, acute: upper teeth shorter, converging, all of equal breadth: the corolla papilionaceous: banner oval, with a broad oblong claw, at the tip emarginate with a point, bent back at the sides, with a longitudinal compressed raised line: wings two, oblong, erect, half-cordate, with an oblong claw, shorter than the banner: keel with an oblong two-parted claw, the belly compressed, semiorbicular, shorter than the wings: the stamina have diadelphous filaments, single and nine-cleft: anthers erect, roundish, four-grooved: a nectareous gland springs from the receptacle between the compound stamen and the germ, short, acuminate: the pistillum is a linear germ, compressed, long: style filiform, shorter, ascending at an erect angle: stigma obtuse, transversely bearded below the tip: the pericarpium is a long legume, coriaceous, one-celled, two-valved, terminated by a point: the seeds several, roundish.

The species cultivated is *V. Faba*, The Bean.

It has an annual root: the stem upright, about two feet high to three or four in the larger garden varieties, thick, angular: the leaves without tendrils: the leaflets about three pairs, ovate-oblong, tomentose, convoluted: the flowers several together in the axils, white with a black silken spot in the middle of the wings: the legumes thick, roundish, straight, pointed, very woolly within, containing several large ovate flattened seeds. It is a native of Egypt.

There are several varieties of garden beans; as the Mazagan Bean, which is the first and best sort of early beans at present known. It is brought from a settlement of the Portuguese on the coast of Africa, just without the Straits of Gibraltar, and smaller than those of the Horse Bean.

The early Portugal or Lisbon Bean, which is the next, and appears to be the Mazagan sort saved in Portugal, as it is very like those which are the first year saved in this country. It is the most common sort used by the gardeners for their first crop, but they are not near so well tasted as the Mazagan.

The small Spanish Bean, which comes in soon after the Portugal sort, and is rather a sweeter bean.

The Broad Spanish, which is a little later than the other, but comes in before the common sorts, and is a good bearer.

The Sandwich Bean, which comes soon after the Spanish, and is almost as large as the Windsor Bean; but, being hardier, is commonly sown a month sooner. It is a plentiful bearer, but not very delicate for the table.

The Toker Bean, which comes about the same time with the Sandwich, and is a great bearer.

The White and Black Blossom Beans, which are also by some much esteemed; the beans of the former, when boiled, are almost as green as peas; and being a tolerable sweet bean renders it more valuable. These sorts are very apt to degenerate, if their seeds are not saved with great care.

The Windsor Bean is allowed to be the best of all the sorts for the table: when these are planted on a good soil, and are allowed sufficient room, their seeds will be very large, and in great plenty; and, when they are gathered young, are the sweetest and best-tasted of all the sorts; but these should be carefully saved, by pulling out such of the plants as are not perfectly right, and afterward by sorting out all the good from the bad beans.

This sort of bean is seldom planted before Christmas, because it will not bear the frost so well as many of the other sorts; so it is generally planted for the main crop, to come in June and July.

And of the small early varieties, there is one which is chiefly planted for curiosity. It is a dwarf, six or ten inches in height, with branches spreading like a fan, and flowers succeeded by small pods, both in clusters; whence it is called Dwarf Fan or Cluster Bean.

Also of the middle-sized later beans, a sort now very commonly cultivated is the Long-podded Bean, a yard or more in height, a great bearer, the pods long and narrow, closely filled with oblong middle-sized seeds. Of this there are several sub-varieties, as the early, the tall, the Turkey, &c.

The White-blossomed Bean, which has none of the black mark on the wings. The seed is semitransparent, and having less of the peculiar bean flavour, when young, than any of the others, is by many in much esteem. It bears abundance of smallish, long, narrow pods, and the seeds are almost black when ripe.

And there is a red-blossomed bean, with smallish pods and seeds, but which is not near so palatable as that with white blossoms.

There are also other varieties.

Culture.—These crops are raised with much facility by sowing them at different times from

October to March, or later. The small sorts are mostly used for the earliest crops, and the first two or three of the above sorts are the most proper for the purpose; but the Mazagan kind is the earliest of all, and most proper to plant for the first crop, and the Portugal and Small Spanish Bean next, all of which should be planted early on warm south borders, or other sheltered sunny exposures, under or near walls, pales, or hedges, or other warm defended quarters, every month from October till the beginning of February; in order that if the first planting should fail by inclement weather in winter, the others may succeed; and if all the crops should survive the frost, they will succeed one another regularly in bearing. The planting should be performed in rows, ranging south and north, two feet and a half asunder, an inch and half deep, and two or three inches apart in each row. They may also be planted in one row length-ways close along under a south wall, &c.

The Dwarf Bean is not proper to be planted for any general crop, only a few for variety; and for which purpose it may be put in in autumn or winter, or in any of the spring or summer months till June or July, in rows two feet asunder, or in patches about the borders.

Of the middle-sized sorts, the Long-pods, Broad-Spanish, and White-blossomed Bean are the best for general culture; though some of all the others may be planted occasionally; and the season for these sorts being put in, is for the first crop in November or December, on a broad warm border, or in any of the most sheltered kitchen-garden quarters, in rows two feet and half or a yard asunder, three inches distance in the row, and two or three inches deep; repeating the planting every month till March, in the open quarters.

Of the large kind, the Sandwich and Toker kinds, being generally more plentiful bearers, and of somewhat less succulent growth than the Windsor, are rather hardier to resist the frost, and may be planted earlier, as before Christmas, for the first crop; and any time after, till May, if required; and of the Windsor, a small or moderate crop may be planted in December, in open mild weather, and a dry soil; in a larger supply in January; and a first full crop in February; and thence in full supplies, of these or any of the other larger sort, every three or four weeks, till the end of April, for the main crops; continuing planting them till the end of May, to have successions as long in the season as possible. These should constantly be planted in open exposures, in rows a yard asunder, or three feet and a half for the large Windsor sort; four or five inches asunder in each row, and three deep.

They succeed in any common soil, but where the land is manured for them it is the best.

The general method of planting them is by the dibble, or in drills; for early planting in dry ground, a shallow drill may be first made, then planting the beans in a row along the bottom, allowing from two to four or five inches distance in the row, according to the size or growth of the different varieties, and from one and a half to three inches deep in the small and large beans; and when the plants are come up about three inches high, they should be landed or earthed up on each side of the row with a drawing hoe, keeping them clear from weeds by occasional hoeing in dry weather; and after having advanced nearly to full growth and in bloom, it is proper to top the plants in general, which throws all the nourishment to the embryo pods, and greatly promotes their setting, and forwards their growth; and in the latter crops prevents their being so much annoyed with the small black fly.

In gathering the crops, avoid pulling up the stems, especially when the land is moist.

VINCA, a genus comprehending plants of the shrubby, evergreen, upright, and trailing kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Contortæ*.

The characters are: that the calyx is a five-parted perianth, erect, acute, permanent: the corolla one-petalled, salver-shaped: tube longer than the calyx, cylindric below, wider above, marked with five lines, the mouth a pentagon: border horizontal, five-parted: segments fastened to the apex of the tube, wider outwards and obliquely truncate: the stamina have five filaments, very short, inflexed and retroflected: anthers membranaceous, obtuse, erect, curved in, fariniferous on both sides at the edge: the pistillum has two roundish germs, with two roundish little bodies lying by their sides: style one common to both, cylindric, length of the stamens: stigma capitate, concave, placed on a flat ring: the pericarpium has two follicles, round, long, acuminate, erect, one-valved, opening longitudinally: the seeds numerous, oblong, cylindric, grooved, naked.

The species cultivated are: 1. *V. minor*, Small Periwinkle; 2. *V. major*, Great Periwinkle; 3. *V. rosea*, Madagascar Periwinkle.

The first has a perennial creeping root, with branched fibres: the whole plant smooth and shining: the stems round, slender, leafy, erect when in flower, from nine inches to a foot in height, and much higher when supported by bushes, marked on each side with a groove faintly impressed; after flowering, prostrate, elongated, taking root at their joints. Accord-

ing to Woodward, the flowering-stem is upright in the spring, but in autumn the flowers are borne on the shoots of the year, which are trailing: the leaves opposite, on footstalks about one-fourth the length of the leaves, which are quite entire, evergreen, shining, somewhat like those of Privet, not having the fringed edge observable in the second sort: the flowers axillary, alternate, solitary, void of scent, on nearly upright peduncles, almost twice the length of the leaves, round, smooth, and shining, pale blue. It is a native of Germany.

It varies in the colour of the flowers; with pale blue, with purple, and white, and with double flowers; and the foliage is sometimes variegated either with white or yellow stripes.

The second species is larger in all its parts than the preceding: the stems erect, finally rooting at the end: the leaves broad-ovate, three inches long and two broad, of a thick consistence, finely fringed with short rigid hairs at the edge, on thick footstalks: the flowers solitary, alternate, on peduncles half the length of the leaves, of a purple blueish colour. It is a native of France, Spain, &c. flowering in May.

The third has an upright branching stem, three or four feet high, when young, succulent, jointed, purple; but as the plant advances the lower parts become woody: the branches have the joints very close, are covered with a smooth purple bark, and have oblong, ovate, entire leaves, two inches and a half long and an inch and half broad, smooth and succulent, setting pretty close to the branches: the flowers axillary, solitary, on very short peduncles: tube long and slender: brim spreading open, flat, divided into five broad obtuse segments, which are reflexed at their points: the upper surface of the petal is of a bright crimson or peach colour, and their under side pale flesh-colour: there is a succession of flowers, from February to the end of October. It is a native of Madagascar, China, &c.

Culture.—These plants are all capable of being increased by layers, cuttings, and suckers.

In the first method, when the layers of the trailing branches are put down into the ground, they readily take root at almost any season. This is very much the case with the first sort, as almost every joint furnishes plants in the course of the summer ready to be put out in the autumn.

The cuttings may be made from the stalks and branches, and be planted in shady borders in the autumn or early spring, where they will become well rooted by the following autumn.

All the sorts succeed in this way.

In the third sort the cuttings should be made from the young shoots and be planted in pots, plunging them in a hot-bed or the bark-bed,

where they will become perfectly well rooted in the same year, and may be potted off separately, being placed in the stove, and shifted as may be necessary into large pots.

This sort may likewise be raised from seed, which should be sown in pots in the early spring filled with light rich earth, covering them well in, and plunging the pots in the hot-bed, or the bark-bed of the stove; and when the plants have a few inches growth, they should be pricked out into separate pots, replunging them in a hot-bed, giving proper shade and water, managing them afterwards as the cuttings.

The suckers may be taken off with root-fibres in the autumn or spring, and planted where they are to grow.

The two first sorts afford variety in the borders, clumps, &c. while the last has a fine effect in stove collections.

VINE. See VITIS.

VINERY, a sort of garden erection, consisting of a wall twelve or fourteen feet in height, extending from east to west, furnished with stoves, and proper flues, with roof and lights of glass, covering a border of some extent; as ten feet or more in width. When vines are to be forced at an early season, upright glasses two and half or three feet in height are often employed in front, to support the roof, and to admit sun and light to the border, which is frequently occupied with low-growing vegetables; but when they are not wanted early, a low wall will answer equally well. In plate D. is seen an improved vinery, or house of this kind; in which fig. 1. shows the elevation: fig. 2, section of the end: fig. 3. section showing the flues: fig. 4. the plan. It has been found to answer well in actual practice. In houses of this sort, supposing the wall to be twelve feet high, the breadth ten feet, and the height of the upright wall in front three feet, the roof will form an angle of about forty-three degrees, which experience has shown to be a suitable pitch for forcing vines with advantage.

These sorts of buildings may likewise be constructed on a plan somewhat similar to that of a single-pitted pine-stove, having the back wall fourteen feet high; the roof slanting, and covering an extent of about sixteen feet; with a flue running from east to west near the front wall. This is well suited not only for grapes, but early crops of melons, strawberries, and other similar kinds.

To save the expense of glass; where there are peach-houses, the glass frames may be also employed for the vinery, when constructed with this intention, and good grapes may be obtained from vines trained against walls about six feet

high, by means of melon-frame glasses, where a small slanting roof is made proper to receive them. But a small degree of fire-heat is of great advantage, and might be applied either by a flued wall, the flue running through the house, or by cast-iron pipes for the purpose.

"These houses," Mr. Nicol says, "vary exceedingly in construction; and although some lay great stress on this article, and there are extremes which ought not to be followed; he is convinced the failure of success, in the production of the grape, is much less a consequence of *bad* construction in the house, than in the preparation of the border, the choice of the kinds, and the general management. It has fallen to his lot to have the construction and management of three several and differently constructed grape houses, in the same garden, under his care, for years, which have equally and uniformly produced excellent crops. This, in his opinion, is a proof of the necessity of a greater niceness in the formation of the border being observed, than in the construction of the house; the fireplace and flues excepted, which should always be particularly attended to."

He also thinks that the site of a vinery is an object of such consequence to the welfare of the plant, and successful cultivation and production of well-flavoured fruit, that the greatest care should be taken in the choice of it. "A gentle hill, having a south aspect, and considerable declivity that way, the soil a strong brown loam of two feet, over a bottom of dry sand, gravel, or soft clay, is, he says, the most desirable, and would be the least expensive of all situations. In this case, the border requires no paving or draining; and admits of a proper mixture of sandy loam, vegetable mould, marle, and dung, by the removal of two feet of the natural bottom, with the natural soil, to form a border, perfectly adapted to the growth of the vine, in the following proportion, viz. One half strong brown loam, a quarter light sandy loam, an eighth vegetable mould of decayed tree leaves, and an eighth stable dung; to which add about a fiftieth part of shell marle. This is the composition, he says, of the vine borders at Wemyss Castle, none of which are less than four feet deep, and one (owing to the accidental situation of the house) is six." See FORCING OF VINES.

In order to form borders against these hot-walls in other cases, they should have the earth taken out two feet deep where the ground is dry, but in other cases one foot will be sufficient, as in wet sills the borders should be raised at least two feet above the level of the ground, to prevent the roots of the vines from being injured by the wet. The bottom of this trench

should be filled with stones, lime rubbish, &c., a foot and a half or two feet in thickness, which should be levelled and beaten down pretty hard, to prevent the roots from running downward. The trenches should be made five feet wide at least, otherwise the roots will in a few years extend themselves beyond the rubbish, and, finding an easy passage downwards, run into the moist ground, and be thereby much injured or destroyed; but before the rubbish is filled into the trench, it is a better method to raise a nine-inch wall, at that distance from the hot-wall, which will keep the rubbish from intermixing with the neighbouring earth, and also confine the roots to the border in which they are planted. This wall should be raised to the height of the intended border, and may be useful to lay the plate of timber of the frames upon, which will be necessary to cover the vines when they are forced; and where the borders are raised to any considerable height above the level of the ground, these walls may preserve the earth of the borders from falling down into the walks; but in carrying them up it will be proper to leave little openings about eight or ten feet distant, to let the water pass off by. As soon as the walls are finished and thoroughly dry, the rubbish should be filled in, as directed above, when there should be fresh light earth laid upon it two feet thick, which will be a sufficient depth of mould for the vines to root in. The borders should be prepared in this manner at least a month or six weeks before the vines are planted, in order that they may have time to settle. See VITIS.

VIOLA, a genus containing plants of the herbaceous fibrous-rooted perennial kind.

It belongs to the class and order *Syngenesia Monogamia* (*Pentandria Monogynia*), and ranks in the natural order of *Campanaceæ*.

The characters are: that the calyx is a five-leaved perianth, short, permanent: leaflets ovate-oblong, erect, more acute at the tip, obtuse at the base, fastened above the base, equal, but variously disposed: of which two support the uppermost petal, two others each a second and third lateral petals, and the remaining one, the two lowest petals together: the corolla five-petalled, irregular: petals unequal: the uppermost petal straight, turned downwards, wider, blunter, emarginate, finishing at the base in a blunt horned nectary, prominent between the leaflets of the calyx: the two lateral ones paired, opposite, obtuse, straight: the two lowest paired, bigger, reflexed upwards: the stamina have five filaments, very small; two of them, which are nearest to the uppermost petal, enter the nectary by annexed appendages: anthers commonly connected, obtuse, increased by

membranes at the tip: the pistillum is a superior germ, roundish: style filiform, prominent beyond the anthers: stigma oblique: the pericarpium is an ovate capsule, three-cornered, obtuse, one-celled, three-valved: the seeds many, ovate, appendicled, fastened to the valves: the receptacle linear, running like a line along each valve.

The species cultivated are: 1. *V. odorata*, Sweet Violet; 2. *V. palmata*, Palmated Violet; 3. *V. pedata*, Multifid-leaved Violet; 4. *V. tricolor*, Pansy Violet or Heart's Ease.

The first has a fibrous whitish root; in old plants the upper part becomes knobby, and appears above ground, the knobs being formed from the base of the petioles which are left yearly; from the bosom of these knobs spring the scions or runners which creep on the ground, and are furnished with leaves and the same kind of stipules which are observable at the bottom of the plant; these runners are very long, and in general do not produce flowers till the second year: the leaves somewhat rounded at the tip, notched at the edge, on the upper side smooth and shining, underneath slightly hairy, when young rolled in at the edges on longish upright nearly smooth footstalks, which sometimes, however, have a few scattered hairs: the stipules from the stump of the root in pairs, lanceolate, toothed, pale: each tooth terminates in a minute gland: the flower-stalks springing from the root, taller than the leaves, smooth, bearing a pair of narrow bractes, pressed to the stalk, and placed above the middle of it: they are incurvated at top, and support one nodding flower of a dark purple colour. It is a native of every part of Europe, flowering in March and April. It is in general very highly esteemed for its fragrance.

There are different varieties: as the single blue and white, the double blue and white, and the pale purple; it is also found with white flowers; and it has been found wild with double flowers. This variety is in much esteem, both for the superior size of the flowers and their extreme fragrantcy; and as they appear later they keep up the succession.

The second species has a perennial root: the leaves five-parted: the segments ovate: the middle segment wider: the outer one toothed only at the base. It is a native of Virginia, flowering here in May and June.

It is curious, and rare in this country, having no sweet scent to recommend it.

The third has the leaves divided into seven parts or lobes, which are sometimes toothed; they are of the sort called pedate: the flowers stand upon naked foot-stalks, are blue, and have

VOL. II.

no scent. It is a native of North America, flowering in June.

The fourth has the stem about four or six inches high, angular, pubescent, at bottom of a dull purple colour: branches alternate, erect: the leaves alternate, petioled, hairy especially about the edge, but sometimes smooth; the lowermost often smaller and roundish, the uppermost narrow and slightly indented: the peduncles alternate, nearly quadrangular, channelled on the back, bent in at top: the petals obcordate, shorter than the calyx, and whitish or yellow-white, in its wild state, but longer than the calyx, and variegated with yellow and purple in gardens. The truly wild plant has sometimes a few purple streaks, and in a somewhat improved state is blue or purplish, with or without yellow or white. It is a native of Europe and Japan, flowering from May to September.

It varies with more than two colours; as purple, blue, yellow, white, improved and enlarged by garden culture.

Culture.—The first sort may be increased by seeds or parting the roots: the seeds may be sown in a bed of light earth, soon after they become ripe, in the beginning of autumn; and when they have some growth be removed into a shady border, until the autumn, when they may be set out where they are to grow. The double-flowered sorts afford no seed. The best mode is, however, by parting the roots in the early autumn, or after they have flowered, and planting them out in the borders, or in beds at good distances, at the latter season watering them well. When intended for flowers they should not be parted oftener than once in three or four years.

The second and third sorts succeed best by being planted in pots filled with loam and bog earth well mixed, plunging them in the mould of a north border, where they should be protected in winter, or removed under a common hot-bed frame.

The fourth sort rises readily from scattered seeds, and may be raised by sowing the seed where the plants are to grow in the autumn or spring.

They may likewise be increased by planting out the off-set slips of the large bushy plants, taken off with root-fibres, in the autumn or spring, in the borders, or in beds for increasing their growth. The varieties may be preserved in this way with safety.

These plants afford variety in the borders and other parts; and the first sort is useful for the flowers.

VITEX, a genus containing plants of the hardy and under-shrubby kinds.

It belongs to the class and order *Didynamia Angiospermia*, and ranks in the natural order of *Personatae*.

The characters are: that the calyx is a one-leaved perianth, tubular, cylindric, very short, five-toothed; the corolla one-petalled, ringent: tube cylindric, slender; border flat, two-lipped: upper lip trifid, with the middle segment wider: lower lip trifid, with the middle segment bigger: the stamina have four filaments, capillary, a little longer than the tube, two of which are shorter than the others: anthers versatile: the pistillum is a roundish germ: style filiform, length of the tube: stigmas two, awl-shaped, spreading: the pericarpium is a globular berry or drupe, four-celled: the seeds solitary, ovate.

The species cultivated are: 1. *V. Agnus castus*, Official Chaste Tree; 2. *V. incisa*, Cut-leaved Chaste Tree; 3. *V. trifolia*, Three-leaved Chaste Tree; 4. *V. Negundo*, Five-leaved Chaste Tree.

The first has a shrubby stalk eight or ten feet high, sending out their whole-length opposite branches, which are angular, pliable, and have a grayish bark: the leaves for the most part opposite upon pretty long footstalks; they are composed of five, six, or seven leaflets, spreading out like the fingers of a hand; the lower ones small, and the middle largest; they are smooth and entire; the largest are about three inches long, and half an inch broad in the middle, ending in blunt points, of a dark green on their upper side, but hoary on their under: the flowers are produced in spikes at the extremity of the branches, from seven to fifteen inches in length, composed of distant whorls; in some plants they are white, in others blue. They are generally late before they appear. They have an agreeable odour when they open fair, and make a good appearance in autumn, when the flowers of most other shrubs are gone. It is a native of Sicily.

There are varieties with narrow leaves, with broad leaves, with blue flowers, and with white flowers.

The second species has the stature of the preceding, but smaller in all its parts, with quinate acuminate pinnatifid leaves pubescent underneath. It is a shrub seldom rising more than three feet high, sending out on every side spreading branches, which are slender and angular: the leaves opposite upon pretty long footstalks; some composed of three, others of five leaflets, which are deeply and regularly cut on their sides, like pinnatifid leaves, and end in acute points: the largest of these leaflets is about an inch and half long, and three quarters of an inch broad in the middle; they are of a dull green colour on their upper side, and gray on their under: the branches are terminated by spikes of flowers three or four inches long, disposed in whorls; in some plants they are white, in others blue, and some have bright red flowers: they are in beauty from the middle of July to the beginning of September. It is a native of China.

The third has the leaflets ovate, acute, quite entire, tomentose underneath, the two nearest to the petiole smaller: the stem is shrubby, branched, round, eight feet high, the thickness of a finger, procumbent, sometimes creeping: the leaves ternate, seldom quinate: leaflets waved, dusky, green above, cinereous-hoary beneath, soft: common petioles long, opposite: the flowers violet in dichotomous, terminating racemes: the fruit small, globular, hard, smooth, black, like pepper, four-seeded. It is a native of the East Indies.

The fourth species has the stem arboreous, twisted, the thickness of the human arm, with spreading branches: the leaflets lanceolate, for the most part quite entire, but sometimes serrate, flat-veined, of a dusky ash colour, on opposite petioles: the flowers purplish, in loose, terminating, erect racemes. It is a native of the East Indies.

Culture.—The first sort may be increased by cuttings and layers: the cuttings should be planted out in the early spring, in a fresh light soil, being often refreshed with water till they have taken root; afterwards the plants must be kept clear from weeds, and be protected during the following winter with mulch or mats; and about the middle of the following March, when the season is fine, be removed into the places where they are to grow, or into the nursery for two or three years to become strong; being pruned up to form regular stems.

The layers of the branches may be laid down in the spring, being careful not to split them,

watering them in dry weather; when in about a year they may be taken off and planted out in the same manner as the cuttings.

The second sort may likewise be increased by cuttings, which should be planted in pots, plunged in a moderate hot-bed, covering them with glasses; when well rooted they may be taken up, and be planted in separate small pots filled with light earth, placing them in the shade till fresh rooted, afterwards placing them in a sheltered situation, with other green-house plants, until the autumn, when they must have protection from frost, and have very little water. They are late in putting out leaves in the spring, so as almost to appear dead.

The third sort is raised from cuttings, which should be planted in pots in the early spring, as April, plunging them in a moderate hot-bed, covering them with hand-glasses, being slightly watered; when they have taken root, they should have free air admitted in a gradual manner; then they may be taken up and planted out in separate pots filled with light earth, replunging them in the bed, and giving due shade. They should afterwards have plenty of free air when the weather is suitable, being treated as tender plants. It must be constantly kept in the stove, having free air in the summer season. It retains its leaves all the year. This may also be raised from layers.

The fourth sort may also be raised from cuttings, in the same manner as the second.

The first sorts may be introduced in the shrubberies, clumps, &c., and the latter kinds afford variety in stove and green-house collections.

VITIS, a genus containing plants of the deciduous climbing kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Heideraceæ*.

The characters are: that the calyx is a five-toothed perianth, very small: the corolla, petals five, rude, small, caducous: the stamina have five awl-shaped filaments, from erect spreading, caducous: anthers simple: the pistillum is an ovate germ: style none: stigma obtuse-headed: the pericarpium is a globular or ovate berry, two-celled: the seeds two, bony, turbinate-cordate, contracted at the base, semibilocular.

The species cultivated are: 1. *V. vinifera*, Common Vine; 2. *V. Indica*, Indian Vine; 3. *V. laciniata*, Parsley-leaved Vine; 4. *V. arborea*, Pepper Vine.

The first is universally known to have a thick twisted irregular weak stem, covered with a brown cloven bark, and having very long tough flexible branches, trailing along the ground, or

climbing trees by means of tendrils: the leaves are lobed and sinuated, serrate, smooth and alternate, on long foot-stalks: the tendrils are opposite to a leaf, and are attended by the flowers in a raceme: the flowers are whitish or herbaceous, very small and insignificant in appearance, but having a very agreeable smell: the petals cohering at the tip and concealing the genitals in manner of a veil, but soon fall off: the berry globular, in some varieties ovate, before it is ripe regularly divided into five cells, but afterwards one-celled, almost pellucid, coloured in some, colourless in others. It is a native of most of the temperate parts of the world. In very cold regions it refuses to grow, and within 25° or even 30° of the equinoctial line, it seldom flourishes so as to produce good fruit. In the northern hemisphere, the proper wine country is from 25° to 51° of latitude.

According to Forsyth, the following are the varieties which are in most esteem in this climate, for the hot-house, vinery, and the natural wall.

SORTS PROPER FOR THE HOT-HOUSE.

The White Muscat of Alexandria, or Alexandrian Frontinac, in which the berries are oval, and the bunches long. It has a rich vinous juice, and is esteemed an exceeding good grape for the hot-house.

The Red Muscat of Alexandria, which resembles the former, only the berries are of a red colour.

The Black Muscadel, which has large oval berries of a black colour and pleasant juice.

The Red Muscadel, which has large red berries of an oval shape, and ripens late; the bunches are very large.

The Black Damascus, which has large, round, black-coloured berries; the flesh is rich and well flavoured. It is an excellent late grape.

The Black Grape from Tripoli, which has large black berries, and is an excellent grape.

The White Hamburgh, which has large oval-shaped berries, and is a pretty good bearer.

The Red Grape, from Syracuse, which is a very fine large grape.

Le Cœur Grape, or Morocco Grape, which has berries of a tawny colour, and is highly esteemed.

The Golden Galician Grape, which has large oval berries of a yellow colour, and tolerable flavour.

The Black Raisin Grape, which has large black berries of an oval form; the skin is thick, and the flesh firm.

The White Raisin Grape, which resembles the preceding; only that the berries are white.

The Malvoise, sometimes called the Blue

Tokay, which has small brownish berries powdered with a blue bloom; the juice is vinous.

The Syrian Grape, which has large, white, oval berries, with a thick skin and hard flesh, and is a good bearer.

The Damson Grape, which has very large berries of a purple colour.

The Cornichon Grape, which has berries of a remarkable shape, long and narrow, of a white colour, with a firm sweet flesh.

The Red Chasselas, which is very like the Chasselas Blanc in size and shape, but is of a dark-red colour; it is a very good grape, but ripens later than the White.

SORTS PROPER FOR THE VINERY.

The Red Frontinac, or Muscat Rouge, which is a very fine grape, and greatly esteemed: it has large brick-coloured berries, and the juice is of a highly vinous flavour.

The Large Black Cluster, which is larger than the former, and has a very rough harsh taste. Mr. Speechly says, that he had this grape from Lisbon, and was assured that it is the grape of which they make red port wine. He has had the same grape eight or ten years.

The White Grape, from Alcobaca, which bears large bunches of white juicy berries.

The White Parsley-leaved Grape, or Ciotat, which has round berries, white, juicy, and sweet. There is a sort of the Parsley-leaved Grape with red fruit.

The White Corinth Grape, which has a small round berry, with a fine juicy flesh of an agreeable flavour.

The St. Peter's Grape, which has a large oval berry, of a deep black colour when ripe; the bunches are large, and the flesh juicy; it ripens late.

SORT PROPER FOR THE WALL.

The White or Common Muscadine, by some called the Chassclas, which resembles the Royal Muscadine, but the berries are smaller; and, although it is not so sweet as the Royal, it is the best grape that we have for a common wall, and a great bearer.

SORTS PROPER FOR THE HOT-HOUSE AND VINERY.

The Black Muscadine, which is a good bearer, and the berries are beautifully powdered with a bluish bloom.

The Royal Muscadine, D'Arboyce, or Chasselas Blanc, which is an excellent grape; the bunches are large, and composed of round amber-coloured berries of a rich vinous taste. In a fine season it ripens in September.

The White Muscat, from Lunel, which has

large oval berries, of an amber-colour, and full of a vinous juice. It is a plentiful bearer, and highly esteemed.

The Black Spanish, or Alicante Grape, which has black berries of a pleasant flavour.

The Black Grape from Lisbon, which has large round juicy berries, and the bunches resemble the Black Hamburgh. It is a good grape.

The Black Frontinac, or Muscat Noir, which has pretty large round berries, black when ripe, and covered with a mealy powder.

The Grizzly Frontinac, which has round berries, of a colour composed of brown, red, and yellow. It has an excellent flavour.

The Black Hamburgh, which has the bunches large, composed of large oval black berries, of a pleasant sweet juice and vinous flavour. It ripens in November.

The Red Hamburgh, which has thin-skinned berries of a dark-red. They have a rich vinous flavour, and ripen about the same time with the former.

The White Morillon, which has an oval-shaped juicy berry, and the leaves are downy on the under side.

The Aleppo Grape, which has middle-sized berries, with a juicy flesh of a very fine flavour. It is a curious grape, frequently striped black and white.

The Genuine Tokay, which is a white grape, with a thin skin, delicate flesh, and agreeable juice.

The Lombardy Grape, which has fine, large, flame-coloured berries, full of a fine juice; and the bunches grow to a great size, frequently weighing more than six pounds.

The Smyrna Grape, which has a large red berry, of a very fine flavour, and is esteemed a very good grape.

The Brick Grape, so called from its colour, has small berries, but the juice is sweet.

The Claret Grape, which has small black berries with a blood-red juice; but the grape is very harsh, if not perfectly ripe.

The Cat's Grape, which has small berries, of a pale-green colour; the flesh is soft and juicy, but of a very disagreeable taste, unless quite ripe.

The Greek Grape, in which the berries are of a blueish white colour; and it is esteemed a fine grape.

The Black Corinth, or Currant Grape, which has a small roundish berry, generally without a stone, of a deep black colour; it has a sweet juice, and ripens in October.

The New Muscat of Jerusalem, which has large round berries of a red colour; some of which, in fine seasons, are as large as a gooseberry; but, as it does not ripen well on

the natural wall in this country, it might be worth while to try it in a hot-house or vinery.

The Black Prince, which has fine large berries, and the bunches grow to a large size: Mr. Forsyth has had them in a favourable season, on the natural wall, weighing a pound and a half; it ripens on the natural wall in October. It deserves a place in the hot-house and vinery.

SORTS PROPER FOR THE VINERY AND WALL.

The July Grape, or Morillon Noir Hatif, is a small round black berry of a sugary juice; and is principally esteemed for being early ripe, which is in September.

The Malmsey Muscadine somewhat resembles the preceding; the juice is very sweet, and of a high flavour. This is a good bearer, and a very fine grape.

The Black Sweet Water has a small roundish berry, of a sweet taste; but, being apt to crack, is not in much repute. The birds are very fond of this grape, which ripens in September.

The Small Black Cluster has small oval berries; the leaves are covered with a hoary down. This is a very pleasant fruit.

The Early White Grape, from Teneriffe; the berries are of a middling size, and the flesh remarkably sweet and juicy.

The Auverna, or True Burgundy Grape, sometimes called the Black Morillon, is an indifferent fruit for the table, but is esteemed one of the best for making wine.

SORTS PROPER FOR THE HOT-HOUSE, VINERY, AND WALL.

The White Sweet Water, which has a large berry of a white colour, and very agreeable juice; it is esteemed an excellent grape, and ripens in September.

The White Frontinac, or Muscat Blanc, which has large bunches composed of round berries: the juice of this grape, when fully ripe, is exquisite.

To this list are added the following sorts, without any descriptions:—

The Black Frankindale, the Black Gibraltar, the Black Muscat of Alexandria, the Miller Grape, the New White Sweet Water, the Pâsse Musk, the Pearl Muscadine, the Red Constantia, the Red Raisin, the Sir Abraham Pitcher's Fine Black, the West's St. Peter, the White Constantia.

The following are the sorts recommended for a small garden, by the same author:—

"The White Muscadine, White Sweet Water, Black Sweet Water, Large Black Cluster, Small Black Cluster, the Miller Grape; and the St. Peter's, and the Black Hamburg, answer well in favourable seasons."

The author of the Scotch Forcing Gardener observes, that "amongst the numerous varieties of grapes, he does not know above eighteen or twenty kinds worth a place in the vinery, and even that number cannot have places in an ordinary-sized house; but where there are two or three houses, a variety to the extent of twenty-four kinds may be encouraged, without transgressing the bounds of moderation." The following is the list which he advises:—

White Sweet Water, White Muscadine, Royal do. Black do. Black Frontinac, White do. Red do. Grisly do. Black Hamburg, White do. White Raisin, Red do. Syrian, White Tokay, Flame-coloured do. White Pâsse Mosque, Grecian, White Muscat of Alexandria, Black do. Large Black Cluster, Black Constantia, White do. St. Peter's Grape, Lombardy.

Out of which, he thinks, the proprietors of grape-houses may choose so as to stock any grape-house.

The second species has the trunk woody, sending out many slender branches furnished with branching tendrils, by which they fasten themselves to trees: the flowers in bunches like those of the other sorts; succeeded by berries or grapes of an austere taste: the size of the common vine, but with gray hairs scattered over the whole: the leaves undivided, almost smooth above, but villose and veined beneath with thick vessels: it has a simple tendril from the axils, and simple raceme from the middle of the tendril: the flowers white, like those of the common vine, and equal, on small lateral racemes: the berries round, brownish-green, small, watery, acid, eatable. It is said to produce a great quantity of small black grapes in the lower hills of Jamaica; but they are of a rough taste, and would doubtless make an excellent red wine if properly managed. It seems to thrive best in the Red-hills. It is there known by the name of Water-witbe. It is a native of the East and West Indies, &c.

The third has the stalks and branches like those of the common grape, but the leaves are cut into many slender segments: the grapes are round, white, and disposed in loose bunches. It is now little known, as the fruit has little flavour, and ripens late in autumn; only a few plants are preserved for the sake of variety.

The fourth species has the stem woody, sending out many slender branches, which climb by tendrils: the leaves are composed of many smaller winged leaves, divided somewhat like those of common Parsley, of a lucid green on their upper side, but much paler on their under: the flowers axillary in loose bunches, very small, white, composed of five small petals, which ex-

pand and soon fall off: they are not succeeded by any fruit in this climate; but the berries which come from North America, their native place of growth, have generally three seeds in each of them.

Culture.—The vine may be increased in different ways: as by seeds, cuttings, layers, as well as grafting and inoculation; but the cutting and layer methods are the most commonly employed.

In raising vines from seeds, they should be sown in the early spring, as about the beginning of March, in small pots filled with mould of the light fresh kind, to the number of three or four seeds in each, plunging the pots in a moderate hot-bed, the mould being gently sprinkled over with water, from a fine-rosed watering pot, every day when the weather is hot and dry, which should be performed in the latter part of the day as the sun disappears from the frame. But when the season is such as to keep the mould in the pots properly moist, the waterings may be omitted. As soon as the waterings have been performed, the frames should be shut down, and be kept in that state during the night when the heat is not too great.

When the heat of the bed begins to decline, a lining of horse dung and fresh leaves should be added; or the heat be renewed by stirring the old beds up and making slight additions to them. This should be continued till the plants have acquired sufficient strength to support themselves without bottom heat.

It will be necessary about the end of August, Mr. Forsyth says, "to take the lights off, that the plants may be hardened before winter, taking care to shelter them in frames covered with mats, which will prevent the frost in the latter end of October and beginning of November from injuring the tender shoots."

And when the plants are about six inches high, they should, he says, "be transplanted singly into deep pots, forty-eights, filled with the same sort of vegetable mould that is directed to be used for vines; taking great care not to hurt the roots, nor to break the leaders; then plunging them again into the hot-beds: but if the heat of the old bed be too much decayed, it will be necessary to have a new one prepared before-hand, to receive the pots as soon as the plants are transplanted. When they grow vigorously, it will also be necessary to shift them into thirty-twos. When the plants are above six inches high, they should, he says, be carefully tied to small rods, leaving only one stem for the first year. The rods should be as high as the frames will permit." And when the leaves begin to drop, they should, he says, "be care-

fully picked off the pots, to prevent the plants from getting mouldy, which would very much injure their growth."

He likewise advises, that they "should be kept under frames, or put into the green-house, in hard winters, to shelter them from severe frosts. In the spring, about March or the beginning of April, if from seed ripened in this country, they may be planted out against the walls where they are to remain; but, if from seed imported from vine countries, he would advise not to plant above one or two against the wall, or in the hot-house, before a specimen of the fruit has been obtained, and proof afforded that the vines are worth cultivation." It is likewise recommended that after they are planted, they should be cut at the third eye, if strong; but at the second, if weakly; at the same time rubbing off the lower bud with the finger and thumb, as directed below.

Where the method by cuttings is made use of, these should be chosen from the shoots that are best ripened, and have the shortest joints; always having one or two joints of the last year's wood, cutting it perfectly smooth and a little rounding at the lower end, and as near to a joint of the old wood as possible. The upper end should also be cut smooth and sloping towards the wall; but if they are planted in beds or borders, the cut should always face towards the north. When cuttings are planted against piers or walls, it should be at about a foot distance from each other, according to the vacant space, and so deep as to have the second eye level with the ground, constantly rubbing off the lower eye; as by this means, where no accident happens to the top bud, there will be a shoot produced from each eye, with a little one under, which should always be rubbed off as soon as it begins to swell; as if suffered to grow to any considerable size there will be danger of injuring the large one in rubbing the small one off. All the runners and side-shoots should likewise be picked off as directed above, leaving only two shoots, which should be trained at their full length. About the beginning of February they may be pruned, leaving one or two eyes on each according to the strength of the shoot, which should be managed as explained below.

"For the first year," Mr. Forsyth says, "especially if the summer be dry, and proper attention be not paid to the watering of them, they will make but little progress; but in the second year it may be plainly discerned which is the strongest plant, which only should, he says, be left to fill up the vacant space on the wall; the rest should be taken up and planted in other situations where they are wanted for fruit."

A method is made use of by Mr. Speechly and others, of propagating the vine from one eye, and a few inches of the preceding year's wood, which they prefer to those raised by cuttings in the common way, on these accounts: "they have more abundant roots, grow shorter jointed, are more prolific, and will, if permitted, come into bearing the second year."

It is advised that choice should be made of cuttings after a warm dry season, when the wood ripens well; each cutting having two inches of the old wood, with one eye of the new. When the vines are pruned there is great choice; they should therefore be then selected of a middling size, the wood round and perfectly ripened.

After this, pots are to be filled with rich light mould, that has been well meliorated and prepared some time before. The cuttings being then prepared for planting, by the bottom part being cut perfectly smooth; if any of the old dead snags remain, they should be cut off close to the quick wood, and the top cut sloping towards the back of the hot-house or frame, when placed in them. Mr. Forsyth recommends "planting only one cutting in each pot, which as to size should be a deep forty-eight; by that means he thinks the plants will grow much stronger and quicker than when many are crowded together, and the sun and air will have a freer admission to ripen the wood; for, when many are planted in one pot, they shade one another, and in a considerable degree prevent the sun and air from passing freely among them. When the plants begin to get strong, and the pots full of roots, it will be necessary to shift them from the forty-eights to thirty-twos." "This mode is," he says, "best adapted for private gardens; but for nurserymen, &c., who raise plants for sale, and cannot conveniently spare so much room, it may be necessary to plant three or more cuttings in each pot."

And in these cases the same rules for watering, transplanting, shifting, &c., are to be attended to as was directed for the seedling plants.

Mr. Forsyth observes, that it is "a method very frequently practised by nurserymen and gardeners, when they wish to have their plants fit for sale the same year, to plant them in pots, and place them in the hot-house among the tan, on the flues, or round the curbs of the pit. And he has seen it employed with great success. In this way they may," he says, "be raised either by planting them singly in small pots, or several in a pot, according to its size, planting them out separately when they have taken root, having a hot-bed ready to plunge the pots in as soon as they are transplanted. In this manner they be-

come much forwarded in their growth, and are before the autumn in a state fit for sale."

In raising vines in the layer manner, the method usually made use of is by stools, in the open quarters of the garden, in the same manner as nursery-men propagate forest-trees and shrubs: but the best way, according to Forsyth, is to take layers from these on walls or palings, training the shoots at full length during the summer; when about the month of February some of the finest and strongest shoots should be chosen, laying them across the foot-path into pots (twenty-fours or sixteens) filled with fresh mould, and plunging them in the ground about two inches below the surface; at the same time making an incision or two in the old wood, or giving it a twist just below a joint; and though they will generally take without notching or twisting, it is nevertheless advised, as the surest way, to have that done. The layers should then be cut, leaving two or three strong eyes upon each. And when the shoots begin to run, they should be tied to long stakes, to prevent their being broken by the wind; all the runners and side-shoots being picked off, leaving only two or three fine strong shoots on each plant, which should be trained at full length during the summer season.

As soon as the shoots are laid down, it will be necessary to mulch them with good rotten dung, or rotten leaves, which will keep the mould moist; and in very dry summers, a good watering should be given once or twice a week: this will wash in the dung or leaves about the roots, and induce the layers to shoot with more vigour. Mr. Forsyth says, "that in this method of laying, two or three rows of layers may be had from one wall: taking care to lay the branches alternately, and to keep the pots plunged about two inches below the level of the ground."

The same writer advises in choosing vines from the nursery, to select "those which have the strongest and longest shoots."

He observes that where the above directions are properly attended to, the plants will be well rooted in the pots before autumn, and fit for planting in vineries, hot-houses, or other situations. And when they are to be planted out, they should, he thinks, be carefully cut off from the mother vine and carried in the pots to where they are intended to be planted; taking care to preserve the balls as much as possible when they are turned out of them.

It is added that "if the season be warm and fine, the grapes of the early kinds ripen very well on these layers before they are taken up; and, if properly managed, they will bear some fruit the first year after planting. One of the

strongest shoots must, he says, be left nearly at full length, cutting it as high as the uppermost full bud, leaving nothing but round well-ripened wood. If there are three shoots, the remaining two should be cut so as to leave only two full eyes upon each, which should be trained at length, as before directed, to produce fine wood for the next year. The shoot which was trained the preceding year should then be cut down, leaving only two strong eyes to produce wood for the following year; and so on every year, cutting the branches alternately: by this means the walls always may be kept covered with fine healthy bearing wood, and a great deal of time be saved in furnishing hot-houses, vineries, and other places. It is remarked that "this method of laying is practised with great success, by many nurserymen in the neighbourhood of London."

In the producing of vines by grafting, choice should be made of cuttings for grafts, or scions, from the best-bearing branches of the sorts intended to be propagated at the season of pruning. In general the bottom part of the last year's shoot is to be preferred; but in well-ripened vigorous wood, any part of the shoot will answer, provided it be not too long jointed. These cuttings should be preserved in pots filled with light sandy earth till the time of grafting.

The periods for performing the operation are different according to the vines; for those in the pinestove, the beginning of January may be proper, but the middle of March for those growing in the open air. In general they should be grafted about three weeks before they begin to break into bud. And upon small stocks not more than an inch in diameter, cleft-grafting is the most proper; but upon larger stocks, whip-grafting is to be preferred. In both methods care should be taken in fitting the stock and scion together, and the operation should be performed with great exactness; fastening them together with bass matting, and covering them with clay in the usual way. After the operation the scion will sometimes begin to push in a few weeks, but it frequently remains dormant two or three months; during this period the stock must be stripped of all its shoots as soon as they appear; and to preserve the scion in a vegetative state, the clay must be kept moderately moist, by wrapping wet moss round it, and by keeping the moss constantly sprinkled with water. And when it has made shoots five or six inches long, the clay and bandage must be carefully taken off.

The method of grafting by approach is advised by some, however, as the best mode of raising vines. In this case it is necessary to have the plant intended to be propagated, in a pot.

Strong plants, that have been two or three years in pots, are to be preferred; but plants from the nursery may be potted, and grafted in the same season, if brought into a hot-house or vinery. It is suggested that fine grapes and good wood may be obtained even the first season, by any of these methods, but particularly by the last; in which it is evident the graft has a double support, as from the stock, and the plant in the pot.

In this sort of grafting the clay and bandage should remain two or three months after the graft has formed an union; for, if it be taken off sooner, the graft will be very liable to spring from the stock. The pot should be plentifully supplied with water till the month of August, when the graft should be separated from the plant in the pot. Two or three inches of wood below the bottom of the graft may be left, but should be taken clean off at the next pruning in winter.

The Syrian Vine is recommended as the most proper for stocks, and plants of this sort raised from seeds are greatly preferable for this purpose to plants raised either from layers or cuttings.

The principal advantages of the grafting mode of raising vines are; that if a wall should have been planted with bad kinds, instead of stubbing them up, and making a new border, by which several years must elapse before the wall can again be completely filled, in this way their nature may be changed immediately; as good grapes may be obtained from the same year's graft; and in a hot-house the grafts, if permitted, will frequently shoot thirty or forty feet the first summer; that in small vineries or frames, where great variety could not be had in the common way, it may be procured by this means on the same plant;—and that of the improvement of the various kinds, particularly the small ones, which generally make weak wood. The method by inoculation may likewise have advantages in some cases of a similar kind.

When any of the vines that have been raised from seed do not prove of a good flavour, they are proper for grafting or inarching the finer sorts of vines on; for, as the coarser sorts grow more vigorously than the finer, they are, on that account, more fit for grafting or inarching.

It is remarked, that "the best manure for vines is a mixture of vegetable mould, rotten spit-dung, and fresh loam (turf and all); this should be thrown in a heap, and frequently turned, for a year or two before it is made use of."

Pruning and Training Vines.—In the management of the vines after being thus raised and

trained, as they rarely produce any bearing shoots from wood that is more than one year old, care should be taken to have such wood in every part of the trees; for the fruit is always produced upon the shoots of the same year, which come out from buds of the last year's wood. The method practised by gardeners is to shorten the branches of the former year's growth, down to three or four eyes, at the time of pruning; though some leave these shoots much longer, and think that by this practice they obtain a greater quantity of fruit: but what is gained in quantity is probably lost in quality; therefore the best method is perhaps to shorten the bearing shoots to about four eyes in length, as the lowermost seldom is good, and three buds are sufficient, as each will produce a shoot, which generally has two or three bunches of grapes: so that from each of those shoots there may be expected six or eight bunches, which is a sufficient quantity. These shoots must be laid in about eighteen inches asunder; as where they are closer, when the side shoots are produced, there will not be room enough to train them against the wall, which should always be provided for; and as their leaves are very large, the branches should be left at a proportionable distance from each other, that they may not crowd or shade the fruit too much.

In the winter pruning of the vines, it is advised to make the cut just above the eye, sloping it backward from it, that, if it should bleed, the sap may not flow upon the bud; and where there is an opportunity of cutting down some young shoots to two eyes, in order to produce vigorous shoots for the next year's bearing, it should always be done, as in stopping of those shoots which have fruit upon them as soon as the grapes are formed, which is frequently practised, it often spoils the eyes for producing bearing branches the following year. The usual season for this pruning is the end of October.

About the end of April, or the beginning of the following month, when the vines begin to shoot, they should be carefully looked over, rubbing off all small buds which may come from the old wood, which only produce weak dangling branches; as also when two shoots are produced from the same bud, the weakest of them should be displaced, which will cause the others to be stronger; and the sooner this is done the better. And in the middle of the last month they should be gone over again, rubbing off and displacing all the dangling shoots as before, and at the same time fastening up all the strong branches, so that they may not hang from the wall; for, if their shoots hang down, their leaves will be turned with their upper surfaces the

VOL. II.

wrong way, and when the shoots are afterwards trained upright, they will have their under surface upward; and until the leaves are turned again, and have taken their right position, the fruit will not thrive; so that the not observing this management will cause the grapes to be a fortnight or three weeks later before they ripen: besides, by suffering the fruit to hang from the wall, and be shaded with the closeness of the branches, it is greatly retarded in its growth; therefore during the growing season you should constantly look over the vines, displacing all dangling branches and wild wood, and fasten up the other shoots regularly to the wall; and towards the middle of June the bearing branches should be stopped, which will improve the fruit, in doing which three eyes should always be left above the bunches. But though this is practised on those shoots which have fruit, it is not to be performed upon those which are intended for bearing the next year, as these must not be stopped until the middle of July, as by stopping them too soon it may cause the eyes to shoot out strong lateral branches, and in that way injure them. In the summer season care should be taken to rub off all dangling branches, and train up the shoots regularly to the wall as before, which greatly accelerates the growth of the fruit, and admits the sun and air more freely to them, which is necessary to ripen and give the fruit a rich flavour; but the branches should not be too much divested of their leaves, as is the practice with some.

Mr. Forsyth has, however, attempted another mode of pruning and training vines, from trials made on vines planted against the piers of a south wall, among peaches, nectarines, and plums, &c., in which the fruit was so small and hard as to be unfit for the table. They had been trained upright, which induced such a luxuriance of growth as made the sap to flow into the branches in the place of the fruit. "He let," he says, "in 1789, two strong branches grow to their full length without topping them in the summer, and in the following year trained them in a serpentine form, leaving about thirty eyes on each shoot, which produced one hundred and twenty fine bunches of grapes, weighing from one pound to a pound and a quarter each. Every one that saw them said that the large ones were as fine as forced grapes; while the small ones produced from branches of the same vine, trained and pruned in the old way, were bad natural grapes, and not above twice the size of large currants. And in order more fully to prove the success of the experiment, he next year trained five plants in the same way, allowing the shoots intended for bearing wood to run

3 U

to their full length in summer, training them wherever there was a vacancy between the old trees; where there was none, he ran them along the top of the wall, without topping them. In winter he trained them in a serpentine manner so as to fill the wall as regularly as possible; they were, he says, as productive as those in the former year. And after a three years' trial, he thought he was warranted to follow the same practice with the whole; when in the year 1793 he sent, he says, for the use of his majesty and the royal family, three hundred and seventy-eight baskets of grapes, each weighing about three pounds, without planting a single vine more than there were the preceding year, in which he was able to send only fifty-six baskets of the same weight; and those so bad and ill-ripened that he was ashamed of them, as they were not fit to be sent to the table."

This, he thinks, sufficiently proves the great advantage that the serpentine method of training possesses over the common method. He advises that the shoots should be brought as near as possible from the bottom of the vine, that the wall may be well covered. When the walls are high, and the shoots from the serpentine branches strong, they are sometimes let remain; but if the walls are low, and the serpentine branches produce weak shoots, they are cut out in the autumnal pruning, and the strongest of the young wood trained up in their room.

As the size and fineness of the bunches of grapes depend in a great measure on the bearing wood being strong and well ripened, great attention should be paid to these circumstances. Where the vines produce small bunches, they should be cut down to two or three eyes, in order to have strong wood for the ensuing year. And as it has been seen that vines bear their fruit on the wood that was produced the preceding year, when there is a great deal of old naked wood on them, as generally is the case, with some small weak shoots at the extremities, they should always be cut down as near to the ground as possible, in which case there will be no fruit for that year. But another mode is sometimes practised, which is to cut every other shoot, leaving the old ones to produce some small grapes; when in the following year there will be plenty of fine wood, provided care be taken to nail in the strongest shoots, and pick off all the side-shoots that are produced from the eyes, pinching them off with the finger and thumb, or cutting them out with a sharp penknife close to the bud or eye; but never twisting them; as by twisting them the bud that produces the grapes the next year is hurt; being always attentive to cut as near to a bud as possible, and taking care to

lay in the wood very thin in the summer season, that the sun and air may be freely admitted to ripen it well, as by these means it will grow very strong. Great care should also be taken to keep the shoots nailed to the wall, which will prevent their being broken by high winds; picking off all the side-shoots every time they are nailed, which should be done several times during the summer months, according to the quickness of their growth. In fine weather they grow so very rapidly that it is necessary to look them over once every fortnight or three weeks to have them in good order. The vines should never be suffered to run together in a cluster, and mat, as it infallibly ruins them for bearing the succeeding year. The shoots that have been trained in a serpentine manner, are advised by Mr. Forsyth to be topped, as soon as the grapes come to the size of very small green peas, at a joint or two above the fruit; but neither the leading shoot, nor that which is intended to bear fruit the next year, should ever be topped.

In the second year Mr. Forsyth never recommends "the pruning of vines to be performed till the beginning of February, except in such seasons as are very forward. It is, however, the common practice with some to begin pruning soon after the fall of the leaf, before the wood becomes hard; but if a frost sets in before the wood is hard, in particular after wet summers and autumns, it is apt to be very much injured; he has frequently seen it almost killed after autumnal pruning. And he observes that there is often fine weather in the months of October, November, and December, with sun and drying winds, which helps to ripen the wood after wet autumns."

It is advised, "when the vine leaves begin to fall, to take a soft broom and sweep them off upwards in a gentle manner, which will be of great service in assisting to harden the wood." In beginning to prune in February, it is recommended always to make choice of the strongest and longest shoots, leaving them as long as the eyes are found good and plump, and the wood round; but by no means to leave them when they become flat, as in that case they seldom bear fruit; and if they do, it will be very small. Mr. Forsyth never lays in any that has less than fifteen, and from that to thirty good eyes, according to the strength of the shoot, which will produce two bunches from every good eye. He has had seventy bunches of grapes from one shoot. The shoots that have borne fruit in the preceding year should be cut out the next year, except where the wall is to be filled and the shoots are very strong. Plenty of fine healthy young wood is easily provided, if care be taken

in the winter pruning; therefore, none should be left but the fine strong wood, cutting constantly at the second, third, or fourth eye; rubbing the lowest bud off, and that which comes out at the joint between the new and last year's wood. By these means as much fruit will, he says, be procured from these short shoots as by the common way of pruning. It is necessary to leave two or three of the strongest shoots for next year's bearing wood, and never to top them. When there is not room to train them, they may be led over the tops of the other trees, if the vines are planted against piers; or be run behind the standards, if there be any, which is generally the case where the walls are high. In this way all the wall will be covered, which will have a very beautiful appearance when the fruit is ripe, besides furnishing a plentiful supply of fine grapes. The shoots at the bottom of the wall may be run behind the dwarf trees, or be tacked down over the top of the wall on the other side where the walls are low. Mr. Forsyth has had very fine grapes on east and west walls, in good seasons, between peaches, plums, &c., particularly when the trees are young. In these cases he advises to "keep cutting in the vines as the other trees grow and fill up the walls. He also trains them over the tops of trees on each side; which, he says, never does any harm to the trees below, provided they are kept nailed to the wall. He has also planted vines between trees on north and east aspects, and trained them over the tops of the south and west walls to fill the upper parts, till the peaches and nectarines cover them." He then cuts away part of the vines, leaving only as many shoots as he may think necessary. "Two years ago, he says, he removed some old apricots that covered a wall about one hundred and sixty-five feet long, and planted them against a new wall, leaving five vines that were planted against the piers. These five plants have, in the course of two years, covered the above wall from top to bottom, and bear plenty of fine grapes every year. He says he also moved an old vine on a wall near to the above, and cut it in pretty close, when it has in three years spread twenty-six yards, and bears very fine fruit. And against one of the piers had, he says, been planted a black Hamburg grape, and at the other side of the same pier a Muscadine, at the distance of about two feet from each other; he pruned them both according to his method, and the second year after, they produced one thousand one hundred bunches of fine grapes." It is added "that he also tried an experiment by taking some shoots from a south wall, opening the ground

deep enough to lay them in across the footpath at the distance of about four feet from the wall, and tied them to stakes, training them as espaliers, laying in the wood as directed for walls, and keeping them as low as possible, that they might not shade the bottom of the wall; he also pruned them as he does those against walls, laying the shoots in very long, except those that were intended to bear fruit next year, from which he took off all the side-shoots and runners against the wall and espaliers. In a favourable season these bear, he says, very fine fruit, better than what is got from the walls by the old method of pruning."

The use of the composition is advised as soon after pruning as possible; for, as the vine is very porous, it soon imbibes the wet and moisture, which brings it quickly to decay. He adds, that "if at any time a vine should be cut late in the season, it will be apt to bleed much; in which case the powder should be applied, repeating the application till the bleeding stops." He states that he "cut two strong vine-branches in the month of June, and three more in July, in very hot weather, on purpose to try the effect of the powder in stopping the bleeding. The sap rose so strong that it worked out at the top in a froth; he applied the powder, which in a short time entirely stopped it." These directions are chiefly for vines on the natural wall, though the same method has been advised to be practised for forced grapes.

Grape-vines require a dry light soil, and such a situation as has a full south aspect.

Mr. Forsyth advises, "after the grapes are set and begin to swell, to water them with the barrow engine, sprinkling them all over the leaves and fruit, pressing the fore finger over the top of the pipe; by which the water can be thrown as fine as small rain, which will wash all the dust off the vines and leaves, that are frequently covered with it, especially where the garden is near a public road. The insects should likewise be washed off the trees. In fine weather he sprinkles all the wall-trees three times a week, which keeps them clear from insects, and promotes the swelling of the fruit; but this operation must never, he says, be performed when the nights are cold and frosty. The sprinkling of the trees should be begun when the sun is in an oblique direction, or gone off the wall, which may be about four o'clock on a south aspect; as by doing it at this time the leaves will have time to dry before night, and so prevent the frost, if there should be any in the night, from injuring them. In very hot and dry weather the trees should have a good bottom watering once

a week, which will forward the swelling of the fruit. Vines require a great deal of watering; but when the fruit is fully swelled, you should leave it off, particularly when the nights begin to get cold, as it would hurt the flavour of the fruit.

"In order to preserve the grapes, as soon as the large fly makes its appearance, plenty of bottles a little more than half filled with some sweet liquor should be provided to entice the flies to enter them, where they will be drowned. The bottles should be hung on the nails at proper distances all over the vines, and also some of them placed at the bottom of the walls. The blue fly comes much earlier than the wasp, and is no less destructive to the fruit. It is therefore necessary to hang up the bottles betimes, in order to destroy as many of them as possible before the wasp makes its appearance, to have the bottles ready for this second enemy.

"When the grapes begin to ripen, the birds begin to attack the fruit; when it is necessary to bag some of your fine handsome bunches, but to bag them all would be an endless trouble where there is a full crop and a large garden.

"Of course where the bunches are very thick, the quickest way is, he says, to cover the trees with nets, or buntine (a kind of stuff of which ships' colours are made), which will admit a free air to the grapes, and dry soon after rain. They will also in the spring, he thinks, be a good covering for the trees, in cold, wet, or snowy weather. The bunches of grapes should always be kept under the shade of the leaves till they begin to ripen; when you may begin to pick off the leaves which cover the fruit (leaving those a little above it to be a shelter from the wet and frost in the nights): this will assist the ripening of the fruit; and take off only a few leaves at a time, according to the quantity of grapes to be gathered at once; by these means the fruit will continue three times as long in succession as it would if the leaves were picked off all at one time. He has often seen all the leaves taken off from the fruit soon after it was set, which prevents it from swelling, and it becomes hard and small, and generally cracks. When the leaves are not too thick, they admit, he says, the rays of the sun to pass through, and a warm glow of heat will be reflected from the wall.

"It is often convenient to let the grapes hang as long on the walls as possible; he has often let them hang till the middle of November, only covering them with nets, or buntine. But when the frost begins to set in sharp, they should then be gathered. Where there are several bunches on one branch it may be cut off, leaving about six inches in length, or more, of the wood, ac-

cording to the distance between the bunches, and a little on the outside of the fruit at each end; both ends being sealed with some common sealing-wax, such as wine merchants use for sealing their bottles with, which you may buy at the wax chandler's; then hang them across a line in a dry room, taking care to clip out, with a pair of scissors, any of the berries that begin to decay or become mouldy, which if left would taint the others. In this way he has kept grapes till the sixth of February; but if they are cut before the bunches are too ripe, they may be kept much longer than that period.

"They may also, he says, be kept by packing them in jars, (every bunch being first wrapped up in soft paper), and covering every layer with bran, which should be well dried before it is used, laying a little of it in the bottom of the jar; then a layer of grapes, and so on, a layer of bran and of grapes alternately, till the jar is filled, then shaking it gently, and filling it to the top with bran, laying some paper over it, and covering the top with a bladder tied firmly on to exclude the air; when the top or cover of the jar should be put on, observing that it fits as close as possible, placing them in a room where a fire is kept in wet or damp weather."

Forcing of Vines.—This is performed in different sorts of buildings, contrived for the purpose; such as hot walls and vineries, as well as by hot-houses or stoves. See VINERY.

In the former cases, when the borders have been prepared and made up in the manner directed under the head Vinery; when proper plants of one or two years growth in pots cannot be procured, cuttings, Mr. Nicol says, should be made use of. Others, however, prefer cuttings in all cases, planting two in each hole, to guard against failure, the weakest, where both grow, being afterwards removed. These should be planted about the beginning of April, being chosen from good bearing vines, and such shoots as are well ripened, otherwise they never make good plants. The distance they should be allowed to remain is about six feet. In planting them out, holes should be opened with a spade, about eighteen inches deep; the cuttings being laid in the holes a little sloping, the earth being then filled into the holes, and gently pressed with the foot to them, and raised in a heap so as just to cover the uppermost eyes, afterwards applying a little mulch on the surface of the ground about them to prevent the sun and air from drying the earth; and when the spring is very dry, a little water should be given once a week.

Under this management they usually make strong shoots the first summer.

Mr. Nicol, where rooted plants are employed, advises the pits to be half filled with vegetable mould, and the plants to be carefully taken out of the pots with thin balls entire, and, unless when rooted, be placed in that manner in the pits, filling them in with vegetable mould, and settling them with a little water. This work, in his opinion, may be performed any time from the beginning of November to the first of March with equal success.

But though the above distance of planting may be proper when the vines are full grown, it may be beneficial to have them put in at half that distance at first; as a crop or two may be obtained before it is necessary to thin them out; two of a kind being placed together for the greater convenience of thinning.

The management of the vines, for the three first years after planting, is the same as practised for those against common walls, which has been described above, being, however, encouraged as much as possible, and the shoots not left too long, or too many in number on each root, that they may be duly ripened and prepared for bearing the fourth year, which is the soonest they should be forced: when any sorts of fruit-trees are forced by fire too young, they seldom continue long in health; so that what fruit they produce is small, and not well-flavoured.

By the middle of June the grapes will be almost full grown, therefore the glasses may be kept off continually in the day time, unless the season be very cold and wet, in which case they must be kept on, and only opened when the weather is favourable; for as the racy vinous flavour of these fruits is increased by a free air, so during the time of their ripening they should have as large a share as the season will admit to be given them.

Mr. Nicol advises "in the first and second seasons, to keep the border in a moderately moist state while the plants are growing; but, after their growth begins to abate, particularly the second season, to withhold the waterings by degrees till it is quite stopped, in order to make them harden and ripen their shoots for the production of a crop the third year. Water frequently with the drainings of a dunghill. And wash with the hand engine twice or thrice a week in the evening, in order to refresh and keep the plants clean. Steaming is, he thinks, unnecessary.

"In the third season, keep the border also in a moderately moist state, till the fruit begin their last swelling. Then give large quantities till they begin to colour; after which, entirely withhold it till the crop is gathered; and then give two or three hearty waterings, to recover the

state the border ought to remain in for the winter."

He likewise advises "to wash twice or thrice a week till the flowers begin to open, then to withhold till the fruit is fairly set; washing again till they begin to colour, and then withhold entirely for the season. And in the interim of washing, to steam every night when the fire is at the strongest, by pouring water on the flues till you cannot see an object at the distance of two or three yards: and repeat this early in the morning, if the temperature of the house require the making of fires, or if there is a sufficient heat in the flues to produce it, even in a middling degree."

The insects which infest the grape house are chiefly the green fly, thrips, red spider, and wasp. The two first are, Mr. Nicol says, "easily destroyed by a fumigation of tobacco; the third is kept under by the engine in summer; and the last, by the destruction of their nests, phials filled with honey and water, or sugar and small beer, and bird-lime. All these methods are, however, sometimes ineffectual for the destruction of wasps where they abound in vast quantity; and their fondness for grapes renders it sometimes necessary to inclose the bunches in bags of gauze, or silken paper, which is a misfortune; as the grapes, by being so much excluded from the action of the sun and air, fall greatly off in flavour."

Birds must also be guarded against by some means or other; such as have been mentioned above.

All sorts of grapes should continue on the trees till fully ripe.

It is advised by some, that these vines should not be forced every year, but under good management every other year, or every third year. Of course, in order to have a supply of fruit annually, there should be a sufficient extent of walling to contain as many vines as are necessary for two or three years; and by having the frames in front moveable, they may be shifted from one part of the wall to another, as the vines are alternately forced. These hot-walls are commonly planted with early kinds of grapes, in order to have them forward in the season; though some think it hardly worth the trouble, in order to have a few grapes earlier by a month or six weeks, than those against common walls. The sorts of vines most useful in this mode of culture have been mentioned above.

After these vines are grown to full bearing, they must be pruned and managed after the same manner as has been directed for those against common walls, with this difference only, that in those seasons when they are not forced,

together till it is uniformly mixed. Where sandy loam cannot be had, common sand may be used; and the mould of rotten sticks or old woods, or from hollow trees, may be substituted for the decayed leaves.

"When the border has been prepared, if the weather permit, the vines may be planted at the end of February or the beginning of March, in the front of the hot-house or stove; having first taken the precaution to put a little moss round the upper part of each stem, with two or three folds of paper over it; tied with bass matting, to prevent the eyes from being injured in putting the plants through the holes in the wall. A hole two feet over, and one foot deep, should be made opposite to each rafter and close to the front wall, making the mould taken out of the holes fine, and adding a little of the compost. Then turn the plant carefully out of its pot, and put the upper part through the hole. If the shoot just reach the bottom of the rafter, when planted, it is sufficient; but as the earth may settle a little, it is better to allow two or three inches more. In closing the mould to the plant care should be taken to preserve the roots, their fibres being exceedingly brittle. Lay a thin coat of rotten dung over the mould, and give the plant a gentle watering; then take off the bandage, and fasten the top of the shoot to the rafter. Only one shoot should remain on each plant. Two may be left for a time; but when one is secure, the other must be taken off, but not close to the old wood, as that would occasion it to bleed, and greatly injure it."

It is observed that "from the time the vines begin to grow, they will require constant watering, especially in dry weather, and before the roots have penetrated sufficiently deep into the border or earth in which they are planted. It is the common practice, in these cases, to train a shoot up to each rafter; and if the rafters be not a sufficient depth to keep the leaves of the vines from touching the glass, to have iron pins of about nine inches in length, fixed at proper distances under each rafter; which should have a small hole or eye at the bottom, through which a small iron rod or strong wire should be thrust, for the support of the branch, which pins or wires should be painted."

Mr. Forsyth, however, remarks that when vines are trained straight up the rafters in this manner, they only throw out a few eyes at the top, the rest of the branch being naked; he therefore advises the serpentine method as much preferable.

The plants often show fruit at one year old, but it should not be suffered to stand, except a single bunch, to ascertain the sort. In the summer season the shoots should be constantly

trained, keeping them regularly fastened to the rafters; divesting them of their wires and lateral shoots; and guarding them well against the red spider and other insects.

The vines may in general be suffered to run two-thirds of the length of the rafters before they are stopped; and those which grow remarkably strong, the whole length. When these shoots are stopped, which is done by pinching off their tops, they will, in general, push out laterals, at three or four eyes on the upper part of the shoot, which should be allowed to grow twelve or fourteen inches before their tops are pinched off; when these in their turn will push out other laterals, which should be pinched off at the second or third joint; and thus the sap may be diverted till the end of the season.

When the leaves begin to fall is the best season for pruning. In the first season, supposing the vines to have grown with equal vigour, the shoots may be pruned alternately to three, four, or five eyes, or about twenty feet; but when they have grown moderately strong, the shoots should be pruned down to about eleven feet; as by this alternate pruning the former shoots will make fine wood for the succeeding season, and the latter will produce a crop of fruit; after which, these fruit-bearing shoots must all be cut down nearly to the bottom of the rafters. But when any of the plants appear weak, and have not made shoots more than eight, ten, or twelve feet long, it will be proper to prune every shoot down to two, three, or four eyes. In performing the work the shoots should be taken off with a clean sloping stroke, about half an inch above the eye, making choice of a bold eye to terminate the shoot, and fastening it to the rafter in a complete manner.

The vines in pine-stoves begin to make weak shoots early in January; the house being then kept warm on account of early crops raised in most hot-houses. But when it is kept to a proper degree of heat for pines during the winter months, they seldom begin to push till about the middle of February. It is usual for them to push only towards the ends of the shoots, the other eyes remaining in a dormant state, and causing a long space of naked wood; but to make them push more generally, as soon as the sap is in motion, the house should be kept for a short time a few degrees warmer than usual. In the morning the thermometer should be 5° or 6° above temperate, and in the day-time the house be kept as warm as the weather will permit. It will also be necessary to guard the stem of the vine on the outside against frost; for one severe night would greatly injure, if not totally destroy, the hopes of a crop. This may be done by

wrapping the part exposed round with moss, fastened thick with bass matting; which covering should remain on till spring frosts are over, and then the stem be washed well to clean it. The vines should be divested of the least promising and supernumerary shoots as soon as possible, and great care should be taken not to leave too abundant a crop; as a few bunches in a high state of perfection are preferable to many in a poor state.

At the time of flowering, should the weather prove hot and dry, with brisk winds; to prevent the berries of different sorts from falling off at the time of their setting, it is proper to water the roots of the vines plentifully, to keep the house as close as the weather will permit, and to water the walks and flues in the hot-house constantly, especially late in the evening, when the glasses should be immediately closed, by which a beneficial sort of dew is produced.

In these situations, when the grapes are at their last swelling, are becoming transparent, and change from green to red or black, and till they are nearly on the point of being ripe, plentiful supplies of water, especially if the season prove hot and dry, should be given to the vines.

After the fruit is cut, no other management is required till the pruning season, but that of taking off the lateral shoots in the same manner as in the preceding case. But in the next winter's pruning all the vines that produced a full crop of fruit, should be cut down nearly to the bottom, that is, to the lowermost summer shoot, which should also be cut down to the first or second eye; while all those that were cut down nearly to the bottom the preceding season, and which will, in general, have made very strong wood, must be left to the length of twenty-one or twenty-two feet each, with the intention of producing a full crop of fruit the following season.

The management of them during the next summer will be nearly the same as in the preceding; only, as they have increased in strength and size, they will be enabled to produce and support a larger burthen of fruit. But the crop should always be proportioned to the size and vigour of the plants; but whilst they are young, great moderation should be used as to the number of bunches that are allowed to stand and ripen. They should be well thinned when the berries are about the size of a small shot. And the main shoulders, as also the less projecting parts of the bunch, should be suspended by small strings to the rafters, and every part raised to a horizontal position. In thinning the berries, great care should be taken to leave all the most projecting ones on every side of the bunch.

VOL. II.

In very close-growing bunches it will be necessary to clip out more than two-thirds of the berries; in some, one half; but in the loose-growing kinds, one third is generally sufficient. By this means the remaining berries will swell well, grow to a great size, and not be subject to rot; as they are apt to do in a hot-house, when they are wedged together in a close manner.

It is observed that "not only the rafters or roof of the hot-house, but the back wall also above the flue, may be furnished with fruit. For this purpose, let every fourth or fifth vine-plant be trained in one shoot quite to the top of the rafter, and then directed sideways ten or twelve feet along the top of the back wall. At the winter's pruning, bring down that part of the shoot perpendicularly, and cut it off at one foot above the top of the flue. The next spring encourage only two shoots from the two extreme or lowermost eyes of each shoot so brought down, and train them in a horizontal direction one foot above the top of the flue. These shoots, however, will grow with greater readiness, if they are trained upwards during the summer; and they may easily be brought to the desired position at the next winter's pruning. They will then form against the back wall the figure of the letter T inverted. And in the next season the horizontal shoots will produce new wood from almost every eye, provided all the shoots be pinched off from every other part as soon as they appear;" laying in the shoots from one to two feet apart, according to the kind of vine. It is advised in these cases, to "train all the shoots in a perpendicular direction, and, provided they are strong and vigorous, to suffer them to grow to the length of five or six feet before they are stopped; but all these must be cut down to two or three eyes at the next winter's pruning." And "only one shoot should be permitted to rise from each spur the following season; and although they will in general be sufficiently strong, and produce two or three bunches apiece, yet only one bunch should remain on each shoot: these will then be large and fine, and the wood will be greatly benefited by such practice. But these shoots must be pruned next winter very differently. One shoot must be left four feet, that next it only a few inches long, and so alternately." It is added that "the vines on the rafters will require a management in future seasons nearly similar to that described above; and though it may not be advisable to prune them alternately so near to the bottom of the rafters as was directed for the two preceding seasons, it will be frequently found necessary to cut an old shoot down to the lowermost summer shoot, as near to the bottom of

3 X

the rafter as can be. The side shoot on the other rafters should not be permitted to ramble over the adjoining lights; but at the end of every season it will be proper to cut such shoots down to the second or third eye next the old wood, provided the bottom eyes are bold and strong: this must be done not only to strengthen the vines, but also to prevent the roof of the house from being too much crowded with old wood. Whilst the vines are young, one rafter will suffice for a vine-plant; but when they become older, they will require a larger space; especially the strong-growing kinds, which produce large leaves and bunches. It will be proper therefore to train shoots sideways on the wall-plate, from the stem of the plant, immediately at its entrance into the house. These shoots should be carried up the adjoining rafters, and the plants growing against such rafters must be taken entirely away; except it should happen that the plant growing against such rafter is trained forward to furnish the back wall. And when a vine-plant occupies two or more rafters, it will be right to prune occasionally, particularly whilst the vine is young, one or more of such shoots down nearly to the bottom of the rafter, as this will not only contribute to strengthen the plant, but afford means to furnish the rafters with a succession of young wood." When the shoots are thus conducted to different rafters, every one may be considered as a separate plant, and be trained up in one shoot; requiring management similar to that mentioned above.

Mr. Nicol, however, rejects the method of planting the vines on the outsides of the houses, and his reasons are these: "first, he thinks it unnatural that one part of a plant should be as it were in Greenland, and the other in the West Indies; and secondly, because he is convinced that no plant (especially the Pine) will live and thrive as well under the shade of another, as when exposed to the free sun and air." To obviate these objections, he plants the vines in the lobbies between the stoves and peach and grape houses; introducing them through the partitions, and training them horizontally on trellises fixed against the back walls and upright sashes in front. By which means he renders each of the stoves as good as any grape-house, without being in the least injurious to the pines.

In these cases, he says, "the front walls of the lobbies were built on pillars; and a border, both without and within, prepared for the plants, in the same manner as for the grape-house." It is added, that in one trial, "the second year after introduction into the stove, the plants completely filled the whole trellis; and a fine crop, the third year, gave a lustre and

richness to the house (in conjunction with a good crop of pines) highly gratifying."

He remarks that "the same methods in regard of watering, washing, and steaming, are to be practised here as in the grape-house. Air is admitted solely for the sake, and to answer the nature, of the pines; the temperature of the house is also regulated for their sakes. But the mode of training and pruning is very different from that in the grape-house. Here, you have it not in your power to bring on vegetation in that slow and regular manner as in the grape-house; and consequently, were the shoots to be laid in at as great lengths, they would only break perhaps a few eyes at the extremities, and the rest remain naked. This he found from experience to be the case; although it did not happen for the first three or four years, owing to the youth and vigour of the plants; but when they had exhausted themselves a little by bearing a few crops, they began to break their buds in the manner above stated. He therefore made it a practice to train them only to five or six feet in summer, and shorten them down to one or two in the pruning season; by which they generally broke all their eyes, and produced plenty of fruit." He further states, that in one house he tried, for two seasons, to produce crops by laterals; but found that method attended with more inconveniency than the above, from the difficulty of procuring a proper succession of strong shoots to produce the laterals, without which they bear very insignificant clusters. He also, in the other house, produced a second crop, for two seasons; but finding it to exhaust the plants very much, he discontinued it; the more especially, as, having so many compartments for grapes, the practice of it was the less necessary. The method is, he says, this: "Just about the time the fruit is half ripe, and when the under part of the shoot is also ripe to the length of about two or three feet, and the extremity of it in a growing state, shorten it at about two or three feet above the ripe part. It will push again, and will generally bring two clusters. Sometimes, also, the second and third eye will push, and bring a cluster or two. In winter pruning, shorten down the first, or spring-made part of the shoot, to two or three feet. This method may be repeated, he thinks, with pretty good success once in two or three years; but, if done every year, it will (in the course of three or four years) occasion the cutting of the plants down to the ground, in order to make them put forth a fresh stock of wood."

He adds that "in the event of severe frost, and the plants being in an early state of vegetation, the border on the outside should be co-

vered with a quantity of stable dung, or long litter, to prevent the roots from being injured by the weather. And unless the plants are wished to produce a second crop, they must not be pruned for good sooner than October; and at the same time, that operation should not be deferred longer than the first of November, lest, when they begin to vegetate, they should bleed. He concludes by observing, that grape vines will bear forcing, and last for many years, when under judicious management."

Besides these modes of cultivating vines, they are capable of being grown with advantages under hand-glasses, so as to produce a few bunches on each plant.

The second species requires artificial heat in this climate, and may be increased from seeds, obtained from abroad, which should be sown in small pots, and be plunged into a hot-bed of tanner's bark. When the plants come up and are fit to remove, they should be each planted out into a separate small pot filled with light earth, and plunged into a fresh hot-bed, shading them from the sun till they have taken new root; when they must be treated in the same way as other tender exotic plants, always continuing them in the stove, otherwise they will not succeed well.

The third should be planted against a wall, and treated in the same way as the common vine, being raised by cuttings or layers in the same manner.

The fourth sort is preserved in some gardens for variety; but it rarely produces flowers in this climate, and has not much beauty. It is increased by laying down the young branches in the spring, which mostly put out roots in one year fit to remove, when they may be taken off and planted out where they are to remain. These require support; and as their young branches are tender, and liable to be killed by frost, they should be planted against a wall, or pale, exposed to the south. The young shoots should be shortened down to two or three buds in the spring, which will cause the shoots of the following summer to be much stronger.

VOLKAMERIA, a genus furnishing plants of the exotic tree kind.

It belongs to the class and order *Didynamia Angiospermia*, and ranks in the natural order of *Personateæ*.

The characters are: that the calyx is a one-leaved perianth, turbinate, five-cleft, nearly equal, acute; the corolla monopetalous, ringent: tube cylindric, twice as long as the calyx: border five-parted, nearly equal, flat: segments reflexed to one side, gaping chiefly on the upper side: the stamina have four filiform filaments, very long, on the gaping side of the corolla: anthers simple: the pistillum is a four-cornered germ: style filiform, length of the stamens: stigma bifid: one of the segments acute, the other indistinct: the pericarpium is a berry (drupe) roundish two-celled, four-grooved: the seed, nut solitary, two-celled, grooved.

The species cultivated are: 1. *V. aculeata*, Prickly Volkameria: 2. *V. inermis*, Ovate-leaved Smooth Volkameria.

The first is a shrub five or six feet high, branched, upright, the whole loaded with white flowers, which have no scent: the stamens most commonly five, but sometimes six, purple: the fruit brown. It is a native of the West Indies.

The second species has the leaves opposite, annual, petioled, bluntish: the peduncles from the upper axils, opposite, solitary, a little shorter than the leaf, three-cleft, three-flowered, more seldom simple and one-flowered: it rises higher than the first sort: the stem and branches are stronger, and grow more erect: the bark is very white: the leaves frequently grow round the branches in clusters or whorls: flowers on long axillary peduncles, supporting several flowers which generally stand erect. It is a native of the East Indies.

Culture.—These plants are increased by cuttings, which should be planted in pots filled with light good mould, in the summer season, plunging them in a moderate hot-bed, covering them close with hand glasses: when they are well rooted, they should be removed into separate small pots, replunging them in the hot-bed till they are fresh rooted; then gradually inure them to the open air in warm weather, continuing them in warm sheltered situations in the open air, till the approach of frosts, when they must be taken into the house where there is a moderate heat. They will not succeed in a common green-house.

They afford ornament among other more hardy stove plants.

WACHENDORFIA, a genus furnishing plants of the exotic flowering perennial kind, for the green-house.

It belongs to the class and order *Triandria Monogynia*, and ranks in the natural order of *Ensatæ*.

The characters are: that the calyx is a two-valved spathe: the corolla six-petalled, unequal: petals oblong, the three upper ones more erect, three lower spreading: nectary of two bristles at the inner sides of the upper petal: the stamina has three filiform filaments, declined, shorter than the corolla: anthers incumbent: the pistillum is a superior germ, roundish, three-cornered: style filiform, declined: stigma simple: the pericarpium is a subovate capsule, three-sided, obtuse, three-celled, three-valved: seeds solitary, rough-haired.

The species cultivated are: 1. *W. thyrsiflora*, Simple-stalked Wachendorfia: 2. *W. paniculata*, Panicked Wachendorfia: 3. *W. hirsuta*, Hairy Wachendorfia.

The first has a thick tuberous root, reed-like, of a deep-red colour, sending out many perpendicular fibres of the same colour, and spreading into several offsets: the leaves, which rise immediately from the root, are large, with five plaited folds; the biggest are two feet long, and three inches broad, of a deep green-colour: the flower-stalk rises from the centre of the heads between the leaves to the height of three or four feet, with leaves of the same form with those below, but narrower, and ranged alternately, embracing the stalk half round with their base: the flowers when young are enclosed in sheaths, which, after some time, open and make way for the flowers to come out; then they wither and dry, but remain upon the stalk like those of the yellow *Asphodel*: they form a loose spike, and there are several upon one common peduncle, which open one after the other: the upper flowers stand almost upright, but the lower nod; they are hairy and of a saffron colour on the outside, but smooth and yellow within. It is a native of the Cape.

The second species, when in flower, is a foot high: the root perennial, a little creeping, furnished with oblong cylindrical and nearly perpendicular tubercles: the leaves radical, two-ranked, sessile, equitant, vertical, spreading, dilated on the inner side at the base, channelled,

linear-lanceolate, pointed, entire, nerved, bright green, very like those of the first, but only one-third of the size, dying soon after the plant has done flowering, and not appearing again for some months: the stalk erect, cylindrical, bearing one or two small leaves, branched, many-flowered: general flower-stalks alternate, spreading, racemose, bearing from three to five flowers, cylindrical, downy: partial ones short, downy, all directed upwards, single-flowered. It is a native of the Cape.

The third seems chiefly to differ from the second in having hairy leaves, a more slender and taller stem, reddish-brown, and not green as in it; its branches more divaricate, the two upper lateral petals more contiguous, and its flowers when closed form a slenderer and more compact column: the incumbent anthers seem also to be shorter and rounder: the root-leaves oblong, lanceolate, three or four, about three or four inches high: the stem about three times their length: the segments traversed longitudinally on the outside by a brown hairy fillet; outer upper one wholly brown and pubescent outwards: the flowers scentless, opening in succession, closing towards evening: they expand in the month of July. It is a native of the Cape.

Culture.—These plants may be increased by offsets, taken from the heads of the roots, in the beginning of autumn, planting them in pots filled with soft loamy earth, mixed with a little sea sand, and when the season proves dry, placing them so as to have only the morning sun, until the offsets have taken new roots, when they must be placed in a sheltered situation, of as to have the full sun. On the approach so frosts, they should be placed in frames, and managed as plants of the tender kind.

The second sort is very impatient of cold, and seldom flowers in this climate.

They produce variety among other potted plants of the green-house kind.

WALK, a dry firm track in the garden or pleasure ground, which is formed of different sorts of materials; as gravel, sand, &c.; but where these cannot be procured, it is sometimes laid with powdered coal, sea-coal ashes, and powdered brick: these are, however, rarely used, when either gravel or sand can be procured. Where sea-coal ashes can be had,

they are preferable to powdered coal or bricks, as they bind very hard, and never stick to the feet in frosty weather. And for wilderness walks they are before most other substances. There are likewise walks sometimes formed of turf, or what are called grass walks. In forming the first sort of walks, when they have been marked out, the earth should be taken away to a certain depth, that the bottoms may be filled with lime rubbish, coarse gravel, flint-stones, or other rocky materials, to prevent weeds from growing through the gravel, as well as to keep away worm-casts. It should be laid ten inches or a foot thick, over which the coat of gravel should be six or eight inches, which should be very fine, but not screened, the large stones only being taken out. When the gravel has been laid to this thickness, they must be exactly levelled, and raked true from all great drips, as well as little holes: by this means most of the stones will be raked under the feet, which may either be evenly sprinkled back over the last length that is raked, or buried in the bottom. Walks are frequently laid too round, so as scarcely to be walked upon with pleasure, and so as to lessen the effect of their breadth. The usual allowance for a gravel walk of five feet breadth, is about an inch rise in the crown: consequently, if twenty feet wide, it will be four inches higher in the middle than on each side; and for twenty-five feet, five inches, for thirty feet, six inches, and so on in the same proportion. When the walk has been carefully laid, trodden down, and raked, either in lengths, or the whole together, it should be rolled well, both in length and cross-ways; the person who rolls wearing shoes with flat heels, that he may not make holes; as, when these are once made in a new walk, they are not easy to roll out again. In order to lay them firm, it will be necessary to give them three or four rollings, after good waterings or heavy rains, as this will cause the gravel to bind, so that when they become dry they will be as hard as terrace. Iron-mould gravel is said to be best for binding, or such as has a little binding loam amongst it; which latter, though it be apt to stick to the heels of shoes in wet weather, nothing binds better in dry weather; and when the gravel is over-sandy or sharp, clay is frequently mixed with it, which, when cast together in heaps and well mixed, binds like a rock: loose gravel is very uncomfortable and uneasy to walk on.

Walks of this sort are not only necessary near the house; but one should always be carried quite round the garden, as being soon dry after rain, and proper for walking on in all seasons. See GARDEN PLAN.

Those about the house should be large, and laid out according to the nature and situation of the ground.

The walks laid with sand or other materials, in the other different parts of gardens or pleasure grounds, should be formed in the same manner, having regard to the nature of the soil, so as to render them as dry as possible at all seasons. The breadth in these walks should be in some measure according to the nature of the ground. Where this is small, five or six feet may be sufficient; but in large grounds much wider, as ten or twelve. In modern grounds of this sort, they are mostly laid out in winding serpentine directions, according to the nature of the sites, so as to have them concealed, and rendered as private as possible, by the trees and plants on their sides; the turns being contrived in as easy and natural a way as can be effected. See GRAVEL.

WALL, a sort of fence erection in gardens, built for the purpose of ripening all such fruits as are too delicate to be perfected in this climate without such assistance. Walls are built with different materials, as stone, brick, &c., according as they can be best procured, and at the cheapest rate. But for fruit-trees, brick is the best, as being not only the handsomest, but the warmest and kindest for the ripening of fruit, as well as affording the best convenience of nailing, for smaller nails will serve in them than in stone walls, where the joints are larger; and brick walls, with copings of free-stone, and stone pilasters or columns, at proper distances, to separate the trees and break off the force of the winds, make not only the most beautiful but the most profitable walls that can be erected.

Sometimes walls are built of mixed materials, as stones and bricks; but in this way they should be carefully built, or the brick front will separate from the stone behind.

Where walls are built entirely of stone, there should be trellises fixed up against them, for the more convenient fastening the branches of the trees: the timbers of these espaliers need not be more than an inch and a half thick, and about two inches and a half broad: these should be fixed across each other, at about four inches distance; for, if they are at a much greater distance, it will be difficult to fasten the shoots of the trees properly. As this trellis will be laid close to the wall, the branches of the trees will lie about two inches from the wall, in which position the fruit ripens better than when it lies quite close to the wall.

Many improvements have been attempted in building walls in different forms, as in semicir-

cular methods, in angles of various forms, and projecting more towards the north, to screen off the cold winds; but not any method has yet been found which succeeds so well as that of making them straight, and building them in an upright manner.

Other schemes of expediting the ripening of fruits on walls have been tried, such as painting them black, or of a dark colour, as the dark colour is supposed to imbibe more of the sun's rays, and retain the warmth longer. This has, however, on the same principle, answered better in theory than practice.

Walls, where substantially built, answer much better than those which are slight, not only in their duration, but also in their warmth. A wall two bricks thick will be found to answer better than one brick and a half; and if in the building of garden walls they are grouted with soft mortar, to fill and close all the joints, the walls will be much stronger, and the air not so easily penetrate through them, as it does through those which are built in the usual manner.

In respect to the aspect for walls in this climate, those which have one point to the eastward of the south are the best, as they enjoy the benefit of the morning sun more, and are less exposed to the west and south-west winds, which are very injurious to fruits, than those which are built due south.

And the next best aspect is due south, and after that the south-east. But as there will, for the most part, be south-west and west walls, these may be planted with some sorts of fruit which do not require so much heat to ripen them as those designed for the best walls: but wherever there are north walls, those will only be proper for baking pears, plums, and morello cherries, for preserving: or duke cherries may be planted against these walls, to continue them longer in the season.

The usual thickness of building walls with brick is thirteen inches, or a brick and a half; but this should be proportionable to the height: for, if they are built twelve or fourteen feet high or more, as is often practised, then the foundations of the walls should be at least two bricks and a half in thickness, and brought up a foot or more above the level of the surface of the ground, of the same thickness; then be set off two inches on each side, which reduces them to two bricks; and five or six feet above the surface of the ground they may be diminished on each side, to reduce them to the thickness of a brick and a half; which must be continued to the top. The piers in these high walls should also be proportionably stronger than is commonly

allowed to lower walls; for, as being more exposed to strong gales of wind, if they are not well built, they are in danger of being blown down. The piers in these cases should be projected the length of a brick in the backside, and the thickness of a brick in the front, and be built about ten or twelve feet asunder.

There is, however, no necessity for building walls higher than nine or ten feet, unless for pears.

In building of hot-walls, the ordinary height is usually about ten feet, which is sufficient for any of those sorts of fruits which are generally forced; for, by forcing the trees, they are mostly weakened in their growth, so that they do not grow so vigorously as those which are exposed to the open air; and where there is not a quantity of walling planted sufficient to let one part rest every other year, the trees are never very healthy, and last but a few years. In these walls the foundations should be made four bricks and a half thick, in order to support the flues; otherwise, if part of them rest on brick-work, and the other part on the ground, they will settle unequally, and soon be out of order; for, wherever there happen any cracks in the flues, through which the smoke can make its escape, it will prevent their drawing; and if the smoke gets within the glasses, it will greatly injure the fruit, and give it a smoky taste. This thickness of wall need not be continued more than six inches above the ground, where the foundation or bottom of the first flue should be, which will be sufficient to raise it above the damps of the earth: then the wall may be set off four inches on each side, which will reduce it to the thickness of three bricks and a half, so that the back wall may be two bricks thick, which is absolutely necessary to throw the heat out more in front; for, when the back walls are built too thin, the heat escapes through them. The wall in front next to the fruit should be only four inches thick, whereby there will be an allowance of nine inches for the flues, which may be covered with twelve-inch tiles; for, if they have an inch and a half bearing on each side, it will be sufficient. The places in which the fires are made must be contrived on the backside of the walls, which should be in number proportionable to the length of the walls. The length usually allowed for each fire to warm is forty feet, though they do very well for fifty feet: they should be shedded over with brick and tile, to keep out the wind and rain, otherwise the fires will not burn equally; and as it is quite necessary to have the fire-places or ovens below the foundation of the first flues, there must be steps down into the sheds, to come to the mouth of them to supply

the fuel; of course they should not be narrower than eight feet in the clear. Where the length of walling requires two ovens, they may be in the middle, being included in one shed, which will save expense, and allow more room to attend the fires; as in this case the sheds must be at least ten feet long, but not more than six in breadth; the steps down being at one end.

In regard to the lower flue through which the smoke first passes from the fire, it may be two feet and a half deep; of course the back wall should be at least two bricks and a half thick, as high as to the top of this flue; and then it may be set off to two bricks, which must be continued to the top of the wall. The second flue, which should return over the first, may be made two feet, the third a foot and a half, and the fourth one foot deep; which four flues, with their coverings, will rise near eight feet in height, so that there will be about two feet left for fixing of the frames at the top to support the glasses, and for the coping of the wall; these four returns will be sufficient to warm the air in the frames. But in the carrying up these walls, some strong iron hooks should be well fastened at convenient distances projecting about two inches from the wall, to which the trellis must be fastened which is to support the trees. The flues must be well pargeted with loam on their inside, and loam be spread under the tiles which cover them, to the thickness of the hooks, that the flues may be very smooth. At each end of these flues small arches should be turned in the back walls, in such a manner that there may be holes opening to clean the flues of soot whenever there is a necessity for it. With respect to the borders in front of these walls, they should be about four feet wide, which will make a sufficient declivity for the sloping glasses; and on the outside of them should be low walls, rising four or six inches above the level of the borders, upon which the plate of timber must be laid, on which the sloping glasses are to rest. The glasses must be divided into two ranges, being contrived in such a manner, as that the upper row may slide down, and be fastened at suitable distances, but the lower may be either fixed or moveable; and the sloping timbers which support the glass frames, must be fastened at bottom into the ground-plate in the front of the border, and at the top into strong iron cramps, fixed in the upper part of the wall for the purpose. They are best made of fir, which does not twist, as oak and some other wood, where it is laid in such position; and on the top should be fixed, in a close manner, a strong board, under which the upper row of glasses should slide, in order to secure the upper part of the glasses

from being raised by the winds, and keep the wet from the trees. It may project on to the glasses about two inches. The width of the frames may be about three feet, or according to the extent of the wall, the bars being placed lengthways of them. See **HOT-WALL**.

WALL TREES, such fruit-trees as are planted against walls, and have their branches trained to them in a fanned regular manner, from three or four to five or six inches asunder, in order to produce their fruits in a superior degree of perfection. They are trees of the more tender kinds, or such as will not ripen their fruits in this climate, unless trained against walls of a southerly aspect, to have the advantage of the full sun; and several sorts of the hardier kinds, to obtain their fruits in earlier maturity, and of an improved growth and flavour. The trees must be trained to south walls for the principal sorts of the more delicate or tenderer kinds, such as peaches, nectarines, apricots, grapes, figs, &c., to have the benefit of the full sun, as they do not ripen in good perfection without this assistance. Some of the best varieties of the principal sorts of the hardier fruit-trees, as the most esteemed cherries, plums, and pears, should be also trained to these walls to produce early fruit in the greatest perfection; also some trees of the choicer sorts of summer and autumn apples, to have the fruit earlier, and of an improved rich flavour for immediate eating; likewise some of the best red and white currants and gooseberries: and on west and east walls to have trees of most of these sorts, to ripen in good perfection, in succession to those on the south walls, especially cherries, plums, and pears, and occasionally some common peaches, nectarines, and apricots; but vines and figs generally on south walls, especially vines, which require all possible benefit of the full sun to ripen the grapes in proper season, and with a rich flavour: the north walls are eligible for any of the common hardier summer and autumn fruits, as cherries, particularly morellos, plums, and pears, for late ripening, to succeed those of the more sunny exposures, and to continue a longer succession of particular sorts, which ripen for immediate eating from the trees; also white and red currants for successional ripening in the autumn. Trees of this sort may be considered as of two orders; common dwarf wall-trees and half-standard wall-trees. See **STANDARD TREES** and **TRAINED TREES**.

The proper season for planting wall-trees is either in autumn, as in October, November, &c., or in spring, as February and March, or not later than the beginning of April, but before that time, if possible; as late spring-planting,

after the young trees begin to push their shoot-buds, is often attended with bad success.

The soil for wall-trees should be a good dry mellow garden earth, not less than one full spade deep; but if two or more, it will be advantageous: or where a good moderately light loamy soil prevails, it is superior for most sorts of fruit-trees; and when enriched by good garden compost it is still more beneficial.

The most proper aspects for the different kinds are as above; and the methods of planting, training, pruning, and nailing, of the different sorts are explained under their particular culture, in the several heads.

WALL-FLOWER. See CHEIRANTHUS.

WALL-PEPPER. See SEDUM.

WALNUT TREE. See JUGLANS.

WALTHERIA, a genus affording plants of the woody exotic kind.

It belongs to the class and order *Monadelphia Pentandria*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a perianth (double: outer one-sided, three-leaved, deciduous; cav. inner) one-leaved, half-five-cleft, acute, cup-shaped, permanent: the corolla has five petals, obcordate, spreading, fastened at bottom to the tube of filaments: the stamina have five filaments, united into a tube, free above, spreading, short: anthers ovate: the pistillum is an ovate germ: style filiform, longer than the stamens: stigmas pencilled: the pericarpium is an obovate capsule, one-celled, two-valved: the seed one, obtuse, wider above.

The species cultivated are: 1. *W. Americana*, American Waltheria: 2. *W. Indica*, Indian Waltheria: 3. *W. angustifolia*, Narrow-leaved Waltheria.

The first has a soft, woody stem, about two feet high, sending out two or three side branches: the leaves alternate, of a pale yellowish green colour; soft and hairy: the flowers collected in a close thick spike at the top of the stem, having soft hairy calyxes: the petals connected at their base, small, bright yellow, spreading. It is a native of South America, &c.

The second species rises with a shrubby branching stalk to the height of eight or ten feet, and is covered with soft hairs: the leaves alternate, petioled, four inches long, and two inches broad in the middle, rounded at both ends, of a yellowish green colour, very hairy and soft, having several longitudinal veins: the heads axillary, sessile, composed of clusters of very small yellow flowers, which just peep out of their soft yellow calyxes. It is a native of India.

The third has woody stalks, six or seven feet high, dividing into several branches, which are

less hairy than those of the second sort: the leaves about three inches and a half long, and an inch and half broad, of a yellowish green colour, not so soft as those of the second, having many veins running from the midrib, standing upon very long footstalks: the flowers very small, yellow, collected into round clusters, standing upon very short peduncles, close to the axils. They appear in June, July, and August. It is a native of the East Indies.

Culture.—These plants may be increased by seeds, which must be sown on a hot-bed; and when the plants are fit to plant out, they must be each removed into a separate small pot, and plunged into a fresh hot-bed, being afterwards treated in the same manner as other tender plants of the same nature, being kept in the bark-stove. In the second year they flower and produce seeds, but may be continued three or four years if they be often shifted, and the roots pared to keep them within compass. In the view of keeping the roots out of the tan, they should be drawn up out of it at least once in six weeks, during the summer season, and the plants be shifted out of the pots once in two months: with this management the second and third sorts may be continued several years, but the first seldom endures longer than two.

They have a good effect in stove collections.

WART-WORT. See EUPHORBIA.

WATER, a well known useful article in gardening, for watering numerous sorts of young plants and trees, seed-beds, &c., especially in the drouthy spring and summer seasons, both such as grow in the full ground, and in pots in the open air, as well as those in green-houses, stoves, hot-beds, &c.: and also in ornamental designs, in pleasure grounds, parks, &c., either when formed into regular pieces, circular, oval, or in oblong or serpentine canals, &c., likewise when varied in a somewhat natural expanse in curves and bendings.

In forming designs of this sort, the nature of the supply should be first considered, whether it be by springs in or near the place, by currents or streams passing through, or so nearly adjacent as to admit of being conducted to the place: or by being conducted from some neighbouring river, brook, or lake, &c., by means of pipes or small cuts, or by being collected issuing from higher grounds, and conducted by proper channels. And another circumstance equally necessary is to consider the means by which it may be retained afterwards. In a loose earthy, sandy, or gravelly bottom, it will soon sink away, especially in dry weather, unless there is a constant current or flow of water running in; but in a naturally strong clayey bottom

of proper thickness both at sides and below, it may be retained in some tolerable degree.

In most cases art, however, will be necessary in this business. See *BASONS*, &c.

Where it is easily attainable in any of the above modes, it should not be omitted, in a smaller or larger scale, especially in grounds of any considerable extent; but where intended principally as reservoirs for watering gardens, they may be of much more moderate dimensions than when designed for ornament; and may be formed either in a circular manner, an oblong canal, pond, or cut, &c., where the supply of water can be most conveniently procured.

Ornamental plats or pieces of water in pleasure-grounds are very desirable, as being great additions to the beauty, variety, and embellishment of them, when properly disposed, and contrasted with some nearly-adjoining detached clumps of plantation, and bounded with a proper expanse of grass ground, spreading from the verge considerably outwards.

In general, when any spaces of water, on a larger or smaller scale, are intended, they should be disposed as conspicuously as possible in some principal division; either sometimes at or near the termination of a spacious open lawn, or occasionally in some other similar open space; and sometimes disposed more or less internally in some central or other grand opening; in all of which, an expanse of water has a fine effect.

The particular forms may be adapted to the nature of the situation, and the extent to that for the supply of water that can be had.

Cascades or waterfalls are also occasionally introduced in extensive pleasure-grounds where there is the advantage of a rivulet, by which they may be formed either in one large fall, or in two or three smaller ones in succession, having large rough stones placed below to break the water, and increase the sound of the torrent in its fall and passage over them, in some degree similar to that peculiar to natural cascades. And fountains, spouting water from images, &c. are sometimes introduced in the centre of small or moderate basins, or other reservoirs of water in gardens, or grounds where a supplying head of water is conveniently situated sufficiently high to raise and throw the water from the jet or spout in a continued full stream to a considerable height, which falling in the basin, keeps the water of it in motion, prevents stagnation, and is thereby rendered more proper for keeping and breeding fish of the gold and silver kinds, &c. and the spouting and falling of the water has a refreshing effect in the heat of summer.

In the business of forming the ground for water, the earth must be excavated to a proper

VOL. II.

depth, gradually sloping from the verge to the middle, from three to four or five feet deep; sometimes, however, in low situations, the place is naturally hollowed in some degree, so as not to require a general excavation, or only in particular parts, and some general regulations to the whole, which in extensive designs is a considerable advantage. Where the sides and bottom are of a sandy, gravelly, or stony nature, or abound in loose soil, and there is not a constant supplying stream, they must be well secured by the application of a thick coat of well-wrought clay. And where this claying is necessary, in the preparatory excavation, a proper allowance should be made for the additional coat of clay, to the extent of twelve or fifteen inches in thickness, and of several inches of gravel over it, to preserve the clay from being wasted by the motion of the water, and keep it clear, which would otherwise be muddy. But previous to the claying, the loose and uneven parts in the bottom and sides of the cavity should be well rammed, to make the whole firm, even, and smooth; then beginning in the middle space with the clay, and proceeding gradually outward, being careful that no stones, sticks, or other matter, get mixed with it, to occasion fissures or cracks, by which the water may escape, laying it evenly, a small thickness at a time, and spreading it regularly, treading it well with the naked feet; and if dry weather casting water on it occasionally, ramming it well from time to time with wooden rammers; then gradually applying more clay, in the same manner, to the proper thickness, being careful that every part is so well puddled and rammed, as not to leave the smallest vacancy. Thus continuing the claying in a regular manner each way from bottom to the top of the circumference, smoothing the surface evenly, and in dry weather covering it, as the work proceeds, with mats or straw litter, or with the stratum of pebbly gravel. When the whole is finished, the water should be let in.

When this has been done, the top or verge must be regulated and levelled, forming it evenly from the edge of the water in a gradual regular expansion to some extent outward, without any stiff slope close to the water, distinct from the surrounding superficies; laying the ground with grass turf, especially along the margin, continuing it as far down as the general level of the water. Where the extent is considerable, it may be sown with grass seeds.

WINTERA, a genus containing a plant of the exotic tree kind.

It belongs to the class and order *Dodecandria Monogynia*, and ranks in the natural order of *Magnoliacæ*.

The characters are: that the calyx is bell-shaped, tri-lobed, with the lobes roundish and concave: the corolla has five oblong, sessile petals, longer than the calyx, and a conical, pitcher-shaped nectarium: the stamina have no filaments; but twelve or sixteen linear, distant antheræ, affixed to the outside of the nectarium: the pistillum is an oval germ, cylindric style, with three obtuse stigmas: the pericarpium is a roundish, trilocular berry, with two heart-shaped seeds.

WOR

The species is *W. Canella*, Wintera, or Bastard Cinnamon.

It rises with a thick woody stem, branching on every side, almost the whole length, growing near twenty feet in height, having a lightish-coloured aromatic bark: the leaves are oblong, obtuse, light-green: the flowers red, in umbellate clusters, at the ends of the branches, succeeded by roundish berries. It is a native of South America.

Culture.—This may be increased by planting cuttings of the shoots in pots filled with mellow loamy mould, plunging them in the bark-bed of the stove. When the plants have attained a good root, they may be removed into separate pots, replunging them in the bark-bed, giving shade and a little water till fresh rooted; being afterwards managed as other woody stove plants. It must always be kept in the stove.

This plant affords variety in the stove among other aromatics.

WINTER-BERRY. See PRINOS.

WOODBINE. See LONICERA.

WOOD, WAXEN. See GENISTA.

WORMWOOD TREE. See ARTEMISIA.

XER

XERANTHEMUM, a genus containing plants of the herbaceous, flowering, annual and shrubby kinds.

It belongs to the class and order *Syngenesia Polygamia Superflua*.

The characters are: that the calyx is a compound flower, having the general calyx composed of many long spear-shaped scales: the corolla is composed of many hermaphrodite florets in the disk, each consisting of one funnel-shaped petal, five-parted at top; and tubular female florets in the radius, more slightly cut at the brim: the stamina five very short filaments, and long cylindric antheræ: the pistillum is a short germen, filiform style, having a bifid stigma in the hermaphrodites; and in the females two reflexed stigmas: there is no pericarpium; each floret succeeded by an oblong, coronated seed, placed on a chaffy receptacle.

The species cultivated are: 1. *X. annuum*, Annual Xeranthemum, or Common Eternal Flower; 2. *X. retortum*, Reflexed leaved Eternal Flower; 3. *X. speciosissimum*, Golden Eternal Flower; 4. *X. Sesamoides*, Silvery Eternal Flower; 5. *X. proliferum*, Proliferous Eternal Flower; 6. *X. vestitum*, Leafy-flowered Eternal

XER

Flower; 7. *X. imbricatum*, Imbricated Eternal Flower.

The first rises with an herbaceous, angular, downy, branching stalk, to the height of two or three feet: the leaves are spear-shaped, spreading, hoary, close-sitting; and all the stalks and branches terminated by large flowers singly, of different colours in the varieties, appearing from July to September, and succeeded by ripe seeds in autumn. It is a native of the Cape.

There are varieties with large white flowers, with purple flowers, with double white flowers, with double purple flowers, and with double violet-coloured flowers.

The second species has under-shrubby trailing stalks, set with recurved, reflexed, hoary-silvery leaves: the flowers come out at the axillas of the branches, having white rays and yellow disks. It is a native of Africa.

The third has an upright shrubby stem, branching three or four feet in height, being set with spear-shaped, trifurcous, sessile leaves; and at the termination of the branches large bright golden-yellow flowers. It is a native of the Cape.

The fourth species has also an upright shrubby

stem, with slender hoary branches, rising three or four feet in height: the leaves small, linear, adpressed, laid close to the branches; and the branches are terminated with large silvery white flowers. This plant is also a native of the Cape.

The fifth has shrubby proliferous stalks: the leaves are granulous-roundish, lightly imbricated: the flowers sitting close to the branches.

The sixth species rises with an upright shrubby stem, branching three or four feet in height: the leaves are linear spear-shaped, mucronated: and the flowers are terminal, leafy, white. It is a native of Africa.

The seventh has the stalks shrubby; and the leaves oval-awl-shaped, smooth, imbricated: the flowers at the end of the branches.

These plants have the name of Eternal Flower, from the circumstance of their continuing long after being plucked.

Culture.—In the first sort and varieties the culture is readily effected by sowing the seeds in pots of light fresh mould in the autumn or spring, or at other seasons for a succession, plunging them in a moderate hot-bed, to bring forward the plants. In the spring they may also be sown in patches where they are to remain, or in beds to be afterwards removed. When the plants have a few inches growth, they should be pricked out in rows a foot apart on beds, or into the borders, clumps, or other places where they are to grow. They should afterwards be kept clean from weeds, and have occasional waterings immediately after pricking out, and afterwards in dry weather.

The other sorts are raised by planting cuttings of the young shoots in the summer in pots filled with light mould, giving them a little water and shade; or, which is better, plunging them into a hot-bed, and covering them with hand-glasses. When they are become firmly established in the autumn, they should be carefully removed into separate pots, being replaced in the hot-bed till re-rooted, after which they should have the management of other shrubby green-house plants.

The first sort produces a fine effect in the borders, clumps, &c. while growing, as well as in pots when the flowers are taken off. And the

other sorts afford variety in green-house collections.

XYLOPIHYLLA, a genus containing plants of the tender exotic kind for the stove.

It belongs to the class and order *Pentandria Trigynia*, and ranks in the natural order of *Euphorbiae*.

The characters are: that the calyx is a six-parted coloured cup: the corolla has no petals; but nectariums composed of six glandules affixed to the germen: the stamina five short filaments and single antheræ: the pistillum is a roundish germ, three short styles, crowned with lacerated stigmas: the pericarpium is a roundish trilobular capsule: the seeds double.

The species cultivated are: 1. *X. longifolia*, Long-leaved Love Flower; 2. *X. latifolia*, Broad-leaved Love Flower; 3. *X. falcata*, Falcated Love Flower.

The first rises with four-angled branches, which are set with long linear leaves. It is a native of America.

The second species also rises with round branches: the leaves are broad spear-shaped. It is a native of the West Indies.

The third has a woody stem and branches: the leaves are linear spear-shaped, shining, placed irregularly: and at the upper part of the branches the flowers are produced upon the edges of the leaves, being very closely placed. It is a native of America.

Culture.—These plants are increased by sowing the seeds in pots in the early spring, and plunging them in a hot-bed: when the plants are come up two or three inches in growth, they should be pricked out in separate pots, replunging them in the hot-bed: they may afterwards be managed as other stove plants of a similar growth.

They are also, some of them, capable of being raised by off-sets, slips, and cuttings, assisted by a hot-bed in the same manner.

They require the constant protection of the stove in winter, but in the hot summer months may be set out in their pots in a sheltered situation, being taken in on the approach of cold nights.

They afford variety, and are curious in stove collections.

YEW TREE. See TAXUS.

YUCCA, a genus containing plants of the succulent, evergreen, shrubby, hardy, and tender kinds.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Lilia*.

The characters are: that there is no calyx: the corolla is monopetalous, bell-shaped, and divided into six large oval segments: the stamina, six very short reflexed filaments, having small antheræ: the pistillum is an oval three-cornered germ, longer than the stamina; no style, but an obtuse three-furrowed stigma: the pericarpium is an oblong, triangular, trifid, trivalved capsule of three cells, containing many seeds lying over one another in a double series.

The species cultivated are: 1. *Y. gloriosa*, Common Adam's Needle; 2. *Y. filamentosa*, Thready Virginian Yucca; 3. *Y. aloifolia*, Aloe-leaved Yucca; 4. *Y. Draconis*, Dragon Tree-leaved Yucca.

The first has an erect, ligneous, thick stem, two or three feet in height, having very long, narrow, stiff, entire leaves, ending in a long, sharp, black spine, garnishing the stem almost to the bottom, and in a large tuft at top: from the centre of the top leaves rises a long branching peduncle, sustaining a panicle of bell-shaped white and purple flowers. It is a native of Canada, flowering in August.

The second species rises with an upright, thick, ligneous stem, two or three feet high, adorned at top with a tuft of very long spear-shaped, stiff, blunt-pointed, sawed, filamentose leaves, emitting long threads from the sides, hanging downward; and from the top of the stem amidst the leaves an erect peduncle or flowerstalk, several feet high, which is set with many large white and purple striped leaves. It is a native of Virginia, flowering in August and September.

The third rises with an erect, thick, fleshy stem, eight or ten feet in height: it is crowned with a large tuft of long, narrow, stiff, crenated, aloe-like leaves ending in sharp spines: from the

centre of the crown of leaves comes out the flowerstalk, branching pyramidally two or three feet in height, having all the branches terminating in a spike of flowers, purple without and white within, appearing in August and September. It is a native of America.

The fourth species has an upright, thick, brown stem, three feet in height, crowned with long, narrow, serrated leaves ending in spines and nodding downward: in the centre of the leaves arises the flowerstalk very branchy, with all the branches terminating in spikes of flesh-coloured flowers, which appear in August and September. It is also a native of America.

Culture.—These plants are all capable of being raised by off-sets or suckers, from the roots and heads of the old plants, as well as by seed.

The off-sets and suckers may be taken off any time in the spring or summer seasons, being laid in some dry place for a few days, till the wounded part caused by the separation from the plant is dried and healed over; when they may be planted out separately in pots of light sandy compost, and be placed in a shady situation till they have taken root in a perfect manner. When assisted by a hot-bed, they often succeed better.

The seed obtained from abroad should be sown in the spring in pots of light earth, plunging them in a hot-bed, in which the plants soon come up; and when they are two or three inches high, they should be pricked out separately in small pots of light sandy mould, re-plunging them in the hot-bed to forward their growth, assisting them with moderate waterings and fresh air daily, and hardening them by degrees to the full air, so as to be set out in June to remain till October, when they should be removed into the green-house for the winter.

Some plants of all the sorts should constantly be preserved in pots.

They are all very ornamental; the two first after they have been hardened, in the dry borders, where the soil is light and where the situation is warm and sheltered; and the others in green-house collections, among other potted plants.

ZANTHOXYLUM, a genus containing plants of the hardy and tender exotic shrubby kinds.

It belongs to the class and order *Diacia Pentandria*.

The characters are: that the male flowers have the calyx a perianthium deeply cut into five oval coloured parts: there is no corolla: the stamina have five awl-shaped erect filaments, with didymous, sulcated, roundish antheræ:—female flower, calyx as the male: there is no corolla: the pistillum, a roundish germen, an awl-shaped style, with an obtuse stigma: the pericarpium, an oblong capsule, formed of two valves and one cell, containing a single smooth roundish seed.

The species cultivated are: 1. *Z. Clava Herculis*, Canada Tooth-ach Tree, or Hercules's Club; 2. *Z. trifoliatum*, Chinese Tooth-ach Tree.

The first grows to the height of twelve feet, with a rough bark armed with short spines: the leaves are winged, of a dark-green colour, growing irregularly on the branches; each consists of four or five pair of spear-shaped folioles, which are terminated by an odd one: the flowers come out from the end of the branches in loose panicles; they are apetalous and have no great appearance, and succeeded by unilocular capsules, containing the seeds. It is a native of North America.

There is a variety; the Ash-leaved Tooth-ach Tree, with oval-oblong folioles, and prickly mid-ribs.

The second species rises with a woody stem, branching several feet in height, being set with trifoliate leaves, composed of three egg-oval folioles. It is a native of China.

Culture.—These plants may be increased by seeds and layers.

The seeds should be sown in the spring, either in an east border, or in pots placed in the morning sun all the summer, being sheltered in a frame in winter; and in the spring following removed to the full air till October, giving proper waterings all the summer; and towards winter be placed again under shelter from frost till March, when the young plants may be potted separately; and thus continued for a year or two, being sheltered in the winter, when they may be transplanted into the shrubbery, where they are to remain.

The layers of the young wood may be laid down in autumn or early spring, and when they

have stricken good root be taken off and managed as the seedlings.

They also succeed by cuttings in spring or summer, planted in pots, assisted by a hot-bed, in which they soon strike, when they should be inured to the full air; and the young plants will be fit for planting out in the autumn, or the spring following.

The first is a very ornamental plant in the borders and other dry parts of shrubberies, and the latter among potted plants in the green house collections.

ZEÄ, a genus containing a plant of the hardy herbaceous annual kind.

It belongs to the class and order *Monœcia Triandria*, and ranks in the natural order of *Gramineæ*.

The characters are: that male and female flowers are separate on the same plant; loosely disposed: the calyx, a bivalve, two-flowered husk: the corolla, two oblong valves, the outward one obtuse and bellied, and the interior bidentated at top, and are inclosed in the calyx, with a very short, diphyllous nectarium: the stamina, three capillary filaments in the males, with bifid prismatic antheræ, opening at top; the female flowers are closely collected in a spike below the males on the same plant: the calyx a single-flowered husk, with two valves; with a corolla, a glumose husk, and four membranous unequal valves: the pistillum, a very small germen, slender pendulous style, and simple stigma: there is no pericarpium: many compressed, roundish seeds, immersed in an oblong, thick five-angled receptacle, forming together a long, thick, close head of corn.

The species cultivated is *Z. Mays*, Maize, or Indian Corn.

It rises with a large, strong, herbaceous stem, ten or twelve feet high, garnished with long, broad, pendulous leaves: male flowers at the upper part of the stalks, in spikes eight or ten inches long; and females arising at the axillas of the leaves below the males, in long, close, thick spikes, covered with thin leaves; and succeeded by numerous seeds placed round the long receptacle in a compact order. Native of America.

There are varieties; with yellowish-white seeds, with deep yellow seeds, and with purple-blue seeds.

Culture.—These plants may be raised by sowing seed in the spring, as March or April, in a dry warm situation, where the plants are intended to remain, in patches, of two or three

seeds or more in each, about an inch and half deep: when the plants are come up, they should be thinned out to one or two of the strongest. But to have the plants more forward, so as to produce ripe seed-spikes more effectually, some should be sown in a hot-bed at the same time, and when the plants are three or four inches high, be forwarded by pricking them out upon another hot-bed, either under a deep frame or an awning of hoop arches to be covered with mats occasionally, allowing them plenty of free air; and when they have sufficient growth, as in May, they may be transplanted, with balls of earth about their roots, into the full ground in the borders or shrubby clumps, in warm sunny situations, being well watered; and when the summer proves warm and dry, they often produce perfect heads, and the seeds ripen in a good manner.

As the plants mostly run up in tall stalks, it is proper to support each with a tall neat stake, especially where much exposed to wind and rain.

These plants in the different varieties have a fine effect in the back parts of borders, clumps, and other places, in warm sheltered situations.

ZINNIA, a genus containing plants of the annual flowering kind.

It belongs to the class and order *Syngenesia Polygamia Superflua*.

The characters are: that the calyx has the general cup oval, cylindric, and imbricated, with many blunt, upright, persistent scales: the corolla compound and radiated, consisting of hermaphrodite florets, placed in the disk, and female ones, which are ligulated, and form the rays: the stamina of the hermaphrodites are five short filaments, with cylindric tubulose antheræ: the pistillum is an oblong aristated germin, with a slender semibifid style, and two erect obtuse stigmas: in the female flowers the germen is oblong and triquetrous, with a capillary style, and two recurved stigmas: the pericarpium has the calyx containing oblong solitary seeds crowned with down, and placed on a paleaceous receptacle.

The species cultivated are: 1. *Z. pauciflora*, Few-flowered Yellow Zinnia; 2. *Z. multiflora*, Many-flowered Red Zinnia.

The first has the root fibrous, from which arises the stalk to about three feet high; it is woody below, and branches upwards, which are placed opposite: these are furnished with oblong leaves of a pleasing green colour: the flowers terminate the ends of the branches on long footstalks; they are of a yellow colour, which decays before the seeds are ripe. It is an annual.

The second species is also annual: the stalk rises erect with upright branches; these are channelled and hairy: the leaves are oval, lanceolate, and placed opposite: the flowers come out at the extreme part of the branches: the florets of the disk are yellow, and those which form the rays are of a dusky red; these continue till the seed is ripe, which is in the autumn.

Culture.—These annual plants are increased from seeds, which should be sown on a slight hot-bed in the early spring, as March, and when the plants are a few inches high, they should be pricked out on another bed previously prepared to receive them, where they should remain till the advance of summer, when they may be taken up and planted out in the borders of the pleasure-ground, where they blow and complete their seeds for the year following.

They have a fine effect in their leaves and flowers in these situations.

ZYGOPHYLLUM, a genus comprising plants of the herbaceous and woody succulent exotic kind.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Rutææ*.

The characters are: that the calyx consists of five oval, obtuse, concave, erect leaves: the corolla has five obtuse petals emarginated at top, and a ten-leaved closed nectarium, which includes the germen: the stamina, ten awl-shaped filaments, and oblong incumbent antheræ: the pistillum, an oblong germen, awl-shaped style, crowned by a simple stigma: the pericarpium, an oval, pentagonous, quinquevalvulous capsule of five cells, having many roundish seeds.

The species are: 1. *Z. Fabago*, Common Bean Caper; 2. *Z. sessilifolium*, African Bean Caper; 3. *Z. Morgsana*, Purslane-leaved Ethiopian Bean Caper; 4. *Z. spinosum*, Thorny Bean Caper; 5. *Z. album*, White Egyptian Bean Caper.

The first has a thick, fleshy, deeply-striking, perennial root: the stalks upright, round, smooth, jointed, herbaceous, green, three or four feet in height, being set with oval, smooth, fleshy, blueish-green leaves, two or three together on each petiole, and reddish flowers by two or three together at the axillas of the stalks, appearing in July, succeeded by long capsules, containing the seed, ripening in autumn. It is durable in root; but the stalks, being herbaceous, perish every autumn. It is a native of Asia.

The second species rises with an upright woody stem, branching numerous and irregularly, three or four feet in height: the leaves oval spear-shaped, thick, smooth, succulent, sessile, surrounding the branches by fours: the flowers yellow, on long slender footstalks at the

sides of the branches, appearing in succession great part of summer. It is a native of Africa.

There are varieties; with yellow flowers, with sulphur-coloured flowers, with white flowers, with copper-coloured flowers, having mostly a reddish or brown spot near the base of each petal.

The third rises with a shrubby stem, dividing and branching irregularly, three or four feet in height: the leaves oval, thick, obtuse, succulent, surrounding the branches by fours: the flowers are sulphur-coloured, on long footstalks from the sides of the branches, appearing most part of summer. It is a native of Africa.

There is a variety with flame-yellow-coloured flowers.

The fourth species has under-shrubby stalks: the leaves close-sitting, with linear acute folioles. It is a native of Africa.

The fifth has the leaves foot-stalked, and clubbed fleshy lobes.

Culture.—The first sort is raised from seeds, which should be sown in the spring in pots filled with light sandy mould, or on a hot-bed. When the plants have a few inches growth, they should be removed into separate pots plunging them into a hot-bed, admitting air so as gradually to harden them to the open ground. They should be protected for a winter or two, and then be

turned out into borders, or other parts, where the situation is warm and the soil dry and rubbishy, as they are of a succulent nature.

The other sorts are capable of being increased by cuttings and seeds; the cuttings should be planted out in the spring or summer in pots filled with light sandy mould, and plunged in a hot-bed, being occasionally watered, when they quickly emit roots, and shoot at top; and when sown in the summer months, they may be planted in a shady place, or in pots placed in the shade, giving frequent waterings, when they will also take good root. In either method, they should be potted off separately towards autumn, in order to be moved into the green-house or glass-case in the beginning of autumn.

The seed should be sown in the spring in pots of light earth, and be plunged in a hot-bed, where they soon come up; when a little advanced in growth, they should be pricked out in separate small pots, being watered and replunged into the hot-bed till well rooted, when they should be gradually hardened to the full air, and in June set out to remain till the autumn, when they should be placed in the green house, or some other place where they may have protection for the winter.

The first sort affords variety in the borders, as well as among potted plants; and the others in collections of the green-house kind.

The following is a Communication received from Mr. BUONAIUTI, Gardener to the Right Honourable Lord HOLLAND, Holland-House, Kensington, which we introduce in the manner it was sent.

DAHLIA. This genus was established by the late Cavanilles, in honour of Dr. Andrew Dahl, a Swedish botanist, and the friend of Baron Alströmer.

It belongs to the class and order *Syngenesia Polygamia Frustranea*, at least in this cold climate.

The stems die every winter, but the root is perennial and tuberos, not very dissimilar to that of the Artichoke.

Four species have been described.

1. *Pinnata*, pinnated as it is called, and figured by Cavanilles in his *Ik. Pl. v. 1. tab. 80.* It is also figured under this name in the 4th vol. of Andrews's *Bot. Repository.* In the *Annales du Mus. National Hist. Nat. v. 3.* M. Thouin calls this species *Purpurea*, but its colour varies from the common *Pinnata*, being very deep; and Mr. R. A. Salisbury suspects that this *Purpurea* of Thouin is the true *Rosea* of Cavanilles. A

paler coloured variety of the *Pinnata*, the seeds of which were sent to Holland-House with the name of *Rosea* by Cavanilles, has been lately figured by Mr. Hooker in the *Paradisus Londinensis*, and described by the above-mentioned botanist, under the name of *Sambucifolia*: that it is not the true *Rosea* of Cavanilles, *Ik.* is unquestionable; for the leaves were simply pinnate, not bipinnate.

2. *Rosea*, Rose-coloured. It is so called and figured by Cavanilles in his *Icones*; but the plant called *Rosea* by M. Thouin in the *Annales*, is most probably the very variety of the first species figured by the name of *Sambucifolia* in the *Paradisus Londinensis*.

3. *Coccinea*, Scarlet. This is figured in Curtis's publication; but we entertain a doubt if it is the same with Cavanilles's plant, if the colour is well copied. The plant, we understand, is dead.

4. *Crocata*, Saffron-coloured. This plant is

not mentioned in any work previous to the *Paradisus Londinensis*, where it is figured and described by the name of *Bidentifolia*. Though the parcels of seeds which came from Cavanilles himself had the title of *Crocata*, the flowers turned out yellow.

It is not intended here to describe minutely these plants; it is sufficient to say, that they elevate themselves majestically like the Holy-hock, and bear both axillary and terminal showy flowers late in the autumn.

Culture.—The first Dahlias introduced into England were lost by taking too much care of them. As they are natives of the hilly parts of Mexico, they will thrive in the open ground very well, and accustom themselves in a very few generations to ripen seeds here annually. By giving the history of those plants which have grown in the gardens of Holland-House, Kensington, it is only meant to offer hints for their culture, leaving the rest to future experience and observation.

On the 20th of May, 1804, the Right Honourable Lady Holland sent home from Spain a parcel of seeds. Though so late in the season, part of them were sown in pots in a hot-bed, and among these was the *Dahlia Pinnata*, with a wrong name on the parcel. When the plant was about fourteen inches high, it was planted in the open ground and grew luxuriantly, pushing up several stems to the height of seven and eight feet. The *Coccinea* and *Crocata*, the seeds of which also came up, but did not grow so full. In the middle of September the first flowers appeared, by which the plant was known to be the *Pinnata* of Cavanilles, and it was figured by Mr. Andrews the same year. The seeds did not ripen, and the roots were taken up on the approach of a sharp frost, and placed in the green-house in a pot for the winter.

In the spring of 1805 all the parcels of seed sent from abroad were sown, and many Dahlias came up among them, which at the time of flowering showed four distinct species or varieties. It seems that Cavanilles, and the French botanists after him, mean to make as many species as there are different coloured Dahlias; but the learned Mr. Salisbury, one of the Vice Presidents last year of the Linnean Society, considers them all simply as varieties of only two distinct species, and has in the *Paradisus Londinensis* named them, not according to their colour, but after the differences of their leaves, being inclined to believe that they will in time vary like the China Aster and Marygold.

And, in fact, with regard to the *Dahlia Pinnata*, now commonly called *Purpurea*, we have great reason to confirm that botanist's suspicion,

having seen nine different varieties of it, either in the colour or multiplication of the petals. The flower, in its natural state, has only eight *ligulated* petals: a few had twelve. There was also one plant with archdouble flowers, exceedingly pale: another with archdouble flowers, exceeding deep purple, exactly like that figured in the *Annales du Mus.* but the flowers were so complicated together, and the autumn of 1805 so cold, they never expanded. We must observe, that the leaves of this plant were bipinnated, but whether it is a real distinct species is not yet positively ascertained.

The *Dahlia Rosea* was last year (1805) the most handsome, and ripened plenty of seeds. The *Purpurea* ripened fewer and weaker seeds, though they now (10th May, 1806) come up freely; the plants, however, look weak. Of the seeds of *Coccinea* and *Crocata*, no plants have yet appeared, though to the eye they seemed as perfect as those imported from Spain.

All the plants of 1805, except one, were taken up before Christmas, and planted in pots or large pans; but though kept in a very cold green-house, they began to push new shoots in the middle of April, and will be planted in the open ground without the help of any artificial heat. Some rich mould round the roots is the only culture they require. The plant left all the winter out of doors was situated close to a south wall; and though it had no covering of any kind, it is now pushing up new shoots. It is necessary to add, that several plants of Dahlias have been raised by cuttings, which are now in good health, and which will probably flower and produce seeds next autumn.

10th July, 1806. Above a hundred plants of Dahlias are now growing in various parts of the gardens at Holland-House in the highest luxuriance: among them are several of the yellow-flowered *Bidentifolia*, raised from seeds saved there last year, though the autumn proved so unfavourable. One plant of the *Purpurea* of Andrews's Bot. Repository is already showing flowers.

The true *Rosea* of Cavanilles, with doubly pinnated leaves, is also growing most vigorously, and one of its stems has been pinched to produce lateral shoots for cuttings. A plant left in the middle of one of the borders of the French garden at Holland-House by mistake, and exposed to the severity of the winter, without any shelter, is as strong and vigorous as any of the other two-year old plants; so that there is not a doubt that this magnificent genus will soon be a common ornament of the gardens in this island.

In plate 19* is a representation of a plant of the *Dahlia Pinnata* or *Purpurea*.

<i>Chenopodium</i>	Goosefoot	<i>Dictamnus</i>	White Dittany
<i>Chiococca</i>	Snowberry Tree	<i>Digitalis</i>	Fox Glove
<i>Chionanthus</i>	Virginian Snowdrop, Fringe Tree	<i>Dionaea</i>	Venus's Fly Trap
<i>Chironia</i>	Chironia	<i>Diosma</i>	Diosma
<i>Chrysanthemum</i>	Chrysanthemum	<i>Diospyros</i>	Indian Date Plum
<i>Chrysobalanus</i>	Cocoi Palm	<i>Dirca</i>	Leather-Wood
<i>Chrysocoma</i>	Goady Locks	<i>Disandria</i>	Disandria
<i>Chrysophyllum</i>	Broad-leaved Star-Apple	<i>Dudartia</i>	Dudartia
<i>Cichorium</i>	Succory, or Endive	<i>Dodecatheon</i>	Virginian Cowslip, or Meadial

INDEX TO THE GENERA OF THE PLANTS.

<i>Dodonea</i>	Dodonea	<i>Helianthus</i>	Annual Sun-Flower
<i>Doronicum</i>	Leopard's Bane	<i>Heliconia</i>	Bastard Plantain
<i>Dracena</i>	Dragon Tree	<i>Helicteres</i>	Screw Tree
<i>Dracopisphalum</i>	Dragon's Head, Balm of Gilead, &c.	<i>Heliotropium</i>	Peruvian Turnsole
<i>Dracoutum</i>	Perforate-leaved Dragon	<i>Helleborus</i>	Winter Hellebore
<i>Ebenus</i>	Ebony	<i>Helonias</i>	Helonias
<i>Echinops</i>	Globe Thistle	<i>Hemerocallis</i>	Day Lily
<i>Ehretia</i>	Ehretia	<i>Hernania</i>	Hernania
<i>Elaeagnus</i>	Wild Olive	<i>Hernandia</i>	Jack-in-a-box Tree
<i>Elephantopus</i>	Elephant's Foot	<i>Hesperis</i>	Night-smelling Rocket
<i>Empetrum</i>	Black-berried Heath	<i>Hibiscus</i>	Hibiscus
<i>Ephedra</i>	Shrubby Horse Tail	<i>Hieracium</i>	Hawkweed
<i>Epicea</i>	Trailing Arbutus	<i>Hippophae</i>	Sea Buckthorn
<i>Eriobium</i>	Willow Herb	<i>Himulus</i>	Hop
<i>Epimedium</i>	Alpine Barrenwort	<i>Hura</i>	Sand-Box Tree
<i>Erica</i>	Heath	<i>Hyoanthus</i>	Hyacinth
<i>Erigeron</i>	Erigeron	<i>Hydrangea</i>	Hydrangea
<i>Erinus</i>	Erinus	<i>Hydrastis</i>	Canadian Yellow-root
<i>Erioccephalus</i>	Erioccephalus	<i>Hymenaea</i>	Locust Tree
<i>Eryngium</i>	Eryngo, Sea Holly	<i>Huacayamus</i>	Common Henbane
<i>Erysimum</i>	Hedge Mustard	<i>Hypericum</i>	St. John's Wort, &c.
<i>Erythrina</i>	Coral Tree	<i>Hysopus</i>	Hyssop
<i>Erythronium</i>	Dog's Tooth Violet	<i>Iberis</i>	Candy Tuft
<i>Eugenia</i>	Eugenia	<i>Ilex</i>	Common Holly
<i>Euonymus</i>	Spindle Tree	<i>Illecebrum</i>	Illecebrum
<i>Eupatorium</i>	Hemp Agrimony	<i>Impatiens</i>	Common Yellow Balsam
<i>Euphorbia</i>	Spurge	<i>Indigofera</i>	Dyer's Indigo
<i>Fagara</i>	Fagara	<i>Inula</i>	Inula
<i>Fagus</i>	Beech Tree	<i>Ipomaea</i>	Ipomaea
<i>Ferraria</i>	Ferraria	<i>Iris</i>	Iris
<i>Ferula</i>	Fennel Giant	<i>Itea</i>	Itea
<i>Ficus</i>	Fig Tree	<i>Iva</i>	False Jesuit's Bark Tree
<i>Fothergilla</i>	Fothergilla	<i>Ixia</i>	Ixia
<i>Fragaria</i>	Strawberry	<i>Ixora</i>	Ixora, or Indian Wild Jasmine
<i>Fraxinus</i>	Ash Tree	<i>Jacquinia</i>	Jacquinia
<i>Fritillaria</i>	Fritillary	<i>Jasminum</i>	Common Jasmine
<i>Fuchsia</i>	Fuchsia	<i>Jatropha</i>	Physic Nut
<i>Fumaria</i>	Fumitory	<i>Juglans</i>	Walnut Tree
<i>Galanthus</i>	Snow Drop	<i>Juniperus</i>	Common Juniper
<i>Garcinia</i>	Garcinia	<i>Justicia</i>	Justicia
<i>Gardenia</i>	Cape Jasmine	<i>Kampferia</i>	Galangale
<i>Genista</i>	Broom	<i>Kalmia</i>	Kalmia
<i>Gentiana</i>	Gentian	<i>Kiggelaria</i>	Kiggelaria
<i>Geranium</i>	Crauc's Bill	<i>Knautia</i>	Knautia
<i>Geum</i>	Herb Bennet	<i>Lachenalia</i>	Lachenalia
<i>Glabolus</i>	Sword Lily	<i>Lactuca</i>	Common Lettuce
<i>Gleditsia</i>	Three-thorned Acacia	<i>Lagerstromia</i>	Lagerstromia
<i>Globularia</i>	Globular Blue Daisy	<i>Lagocchia</i>	Wild Cummin
<i>Gloriosa</i>	Superb Lily	<i>Lantana</i>	Lantana
<i>Gloxinia</i>	Gloxinia	<i>Lathyrus</i>	Everlasting Pea
<i>Glycine</i>	Glycine or Kidney Bean Tree	<i>Lavandula</i>	Common Lavender
<i>Glycyrrhiza</i>	Common Liquorice	<i>Lavatera</i>	Lavatera, Tree Mallow
<i>Gnaphalium</i>	Tree Everlasting	<i>Laurus</i>	Common, Sweet Bay
<i>Gomphrena</i>	Annual Globe Amaranth	<i>Lawsonia</i>	Lawsonia
<i>Gordonia</i>	Loblolly Bay	<i>Ledum</i>	Marsh Ledum, or Wild Rosemary
<i>Gorteria</i>	Gorteria	<i>Lepidium</i>	Common Cress
<i>Gossypium</i>	Cotton Shrub	<i>Leucopium</i>	Great Snow Drop
<i>Grewia</i>	Grewia	<i>Ligusticum</i>	Common Lovage
<i>Guaicum</i>	Lignum Vita	<i>Ligustrum</i>	Common Privet
<i>Gutlandina</i>	Banduc, or Nicker Tree	<i>Lilium</i>	Lily, Common White, &c.
<i>Hemeranthus</i>	Blood Flower	<i>Limodorum</i>	Limodorum
<i>Hematoxyllum</i>	Blood Wood, or Logwood Tree	<i>Linum</i>	Flax
<i>Halesia</i>	Snow-Drop Tree	<i>Liquidambar</i>	Liquidambar
<i>Halleria</i>	African Fly Honeysuckle	<i>Liriodendrum</i>	Tulip Tree
<i>Hamamelis</i>	Witch Hazel	<i>Lobelia</i>	Cardinal Flower
<i>Hedera</i>	Common Ivy	<i>Lonicera</i>	Honeysuckle
<i>Hedysarum</i>	French Honeysuckle	<i>Loranthus</i>	Loranthus

INDEX TO THE GENERA OF THE PLANTS.

<i>Lotus</i>	Bird's Foot Trefoil, Winged Pea	<i>Oryza</i>	Rice
<i>Lunaria</i>	Honesty	<i>Osteospermum</i>	Osteospermum
<i>Lupinus</i>	Lupine	<i>Oxyria</i>	Poet's Cassia
<i>Lychnis</i>	Lychnis, Wild Campion	<i>Othonna</i>	Ragwort
<i>Lycium</i>	Box Thorn	<i>Oxalis</i>	Wood Sorrel
<i>Lysimachia</i>	Louse Strife		
<i>Lythrum</i>	Willow Herb	<i>Pæonia</i>	Peony
		<i>Panax</i>	Panax
<i>Magnolia</i>	Magnolia	<i>Pancratium</i>	Pancratium
<i>Mahernia</i>	Mahernia	<i>Pandanus</i>	Pandanus
<i>Malope</i>	Malope	<i>Papaver</i>	White Poppy
<i>Malyghia</i>	Barbadoes Cherry	<i>Parietaria</i>	Tree Pellitory
<i>Malva</i>	Mallow	<i>Parkinsonia</i>	Parkinsonia
<i>Mammea</i>	Mammea Tree	<i>Parthenium</i>	Parthenium
<i>Mangifera</i>	Mango Tree	<i>Pascerina</i>	Sparrow Wort
<i>Maranta</i>	Indian Arrow Root	<i>Passiflora</i>	Passion Flower
<i>Marrubium</i>	Horehound	<i>Pastinaca</i>	Parsnip
<i>Martynia</i>	Martynia	<i>Pelargonium</i>	Crane's Bill, &c.
<i>Massonia</i>	Massonia	<i>Pentapetes</i>	Pentapetes
<i>Matricaria</i>	Common Feverfew	<i>Pentstemon</i>	Bastard Asarum
<i>Mauritia</i>	Maiden-hair Tree	<i>Periploca</i>	Periploca
<i>Medeola</i>	Medeola	<i>Petiveria</i>	Gumen-Hen Weed
<i>Medicago</i>	Tree Medic	<i>Petrea</i>	Petrea
<i>Melastoma</i>	American Gooseberry	<i>Phaseolus</i>	Kidney Bean
<i>Melia</i>	Bead Tree	<i>Philadelphus</i>	Syringa, Mock Orange
<i>Melianthus</i>	Honey Flower	<i>Phillyrea</i>	Phillyrea
<i>Melissa</i>	Baum	<i>Phlomis</i>	Phlomis
<i>Melittis</i>	Bastard Baum	<i>Phlox</i>	Lychnidea, or Bastard Lychnis
<i>Menispermum</i>	Moon-Seed	<i>Phlox</i>	Date Plum Tree
<i>Mentha</i>	Mint	<i>Phlyca</i>	Phlyca
<i>Mesembryanthemum</i>	Fig Marigold	<i>Phyllanthus</i>	Sea-side Laurel
<i>Mespilus</i>	Medlar	<i>Phyllis</i>	Bastard Hare's Ear
<i>Mesua</i>	Indian Mesua	<i>Physalis</i>	Winter Cherry
<i>Michauxia</i>	Michauxia	<i>Phytolacca</i>	Phytolacca
<i>Michelia</i>	Indian Michelia	<i>Pimpinella</i>	Anise
<i>Mimosa</i>	Mimosa	<i>Pinus</i>	Wild Pine Tree, Fir, &c.
<i>Mimulus</i>	Monkey-Flower	<i>Piper</i>	Black Pepper
<i>Mirabilis</i>	Marvel of Peru	<i>Piscidia</i>	Jamaica Dogwood Tree
<i>Moluccella</i>	Molucca Baum	<i>Pisonia</i>	Prickly Pisonia
<i>Momordica</i>	Male Balsam Apple	<i>Pistacia</i>	Pistacia
<i>Monarda</i>	Monarda, Lion's Tail	<i>Pisum</i>	Common Pea
<i>Monsonia</i>	Monsonia	<i>Platanus</i>	Plane Tree
<i>Moræa</i>	Moræa	<i>Plinea</i>	Plinea, or Myrtle
<i>Morina</i>	Morina	<i>Plumbago</i>	European Leadwort
<i>Morus</i>	Mulberry Tree	<i>Plumeria</i>	Plumeria
<i>Musa</i>	Banana Tree	<i>Polemonium</i>	Polemonium, Greek Valerian
<i>Myrica</i>	Candleberry Myrtle	<i>Polyanthes</i>	Indian Tuberose Hyacinth
<i>Myrsine</i>	African Myrsine	<i>Polygala</i>	Polygala, Milk Wort
<i>Myrtus</i>	Common Myrtle	<i>Polygonum</i>	Knot Grass, Persicaria
		<i>Populus</i>	Poplar Tree
<i>Napæa</i>	Napæa	<i>Portlandia</i>	Portlandia
<i>Narcissus</i>	Common Daffodil, &c.	<i>Portulaca</i>	Purslane
<i>Nepeta</i>	Common Catmint	<i>Portulacaria</i>	African Purslane Tree
<i>Nerium</i>	Common Rosebay	<i>Potentilla</i>	Cinquefoil
<i>Nicotiana</i>	Tobacco	<i>Poterium</i>	Garden Burnet
<i>Nigella</i>	Fennel Flower	<i>Prasium</i>	Hedge Nettle
<i>Nolana</i>	Nolana	<i>Primula</i>	Primrose, Auricula
<i>Nyctanthus</i>	Nyctanthus	<i>Prinos</i>	Winter Berry
<i>Nymphæa</i>	Water Lily	<i>Protea</i>	Protea
<i>Nyssa</i>	Tupelo Tree	<i>Prunus</i>	Plum Tree, Apricot, Cherry Tree, &c.
		<i>Puidium</i>	Guava Tree
<i>Ocimum</i>	Basil, or Basilicum	<i>Psoralea</i>	Psoralea
<i>Oenothera</i>	Tree Primrose	<i>Ptelea</i>	Ptelea, or Shrubby Trefoil
<i>Olea</i>	European Olive	<i>Pulmonaria</i>	Lungwort
<i>Oenonis</i>	Rest Harrow	<i>Punica</i>	Pomegranate Tree
<i>Ophioxylum</i>	Ophioxylum	<i>Pyrus</i>	Pear Tree, Apple Tree, and Quince
<i>Ophrys</i>	Ophrys, or Twayblade		
<i>Orchis</i>	Orchis	<i>Quercus</i>	Oak Tree
<i>Origanum</i>	Origanum, or Marjoram		
<i>Ornithogalum</i>	Star of Bethlehem	<i>Ranunculus</i>	Garden Ranunculus
<i>Orobus</i>	Bitter Vetch	<i>Raphanus</i>	Garden Radish

INDEX TO THE GENERA OF THE PLANTS.

<i>Rauwolfia</i>	Rauwolfia	<i>Staphylea</i>	Bladder Nut
<i>Reseda</i>	Sweet Reseda, or Mignonette	<i>Statice</i>	Thrift, or Sea Gilliflower, Pink
<i>Rhamnus</i>	Buckthorn, Alaternus, &c.	<i>Strelitzia</i>	Strelitzia
<i>Rheum</i>	Rhubarb	<i>Stuartia</i>	Malacodendron
<i>Rhexia</i>	Rhexia, American Soapwort	<i>Syrax</i>	Storax
<i>Rhodola</i>	Yellow Roseroot	<i>Sacetenia</i>	Mahogany Tree
<i>Rhododendrum</i>	Rhododendron, Dwarf Rose Bay	<i>Symphitum</i>	Comfrey
<i>Rhus</i>	Sumach, Poison Tree	<i>Syringa</i>	Lilac
<i>Ribes</i>	Currant Tree, Gooseberry		
<i>Ricinus</i>	Common Palma Christi	<i>Tabernaemontana</i>	Tabernaemontana
<i>Rivinia</i>	Rivinia	<i>Tageles</i>	French and African Marygold
<i>Robinia</i>	False Acacia	<i>Tamarindus</i>	Tamarind Tree
<i>Rondeletia</i>	Rondeletia	<i>Tamarix</i>	Tamarisk
<i>Rosa</i>	Rose Tree and Sweet Brier	<i>Tamus</i>	Black Bryony
<i>Rosmarinus</i>	Rosemary	<i>Tanacetum</i>	Tansy, &c.
<i>Royena</i>	African Bladder Nut	<i>Tarchonanthus</i>	Shrubby African Flea-Bane
<i>Rubia</i>	Dyer's Madder	<i>Torus</i>	Yew Tree
<i>Rubus</i>	Raspberry, Bramble	<i>Telephium</i>	True Opine
<i>Rudbeckia</i>	Rudbeckia	<i>Tetragonia</i>	Tetragonia
<i>Rumex</i>	Sorrel, Dock	<i>Tracrium</i>	Germander
<i>Ruscus</i>	Butcher's Broom	<i>Thalictrum</i>	Meadow Rue
<i>Ruta</i>	Rue	<i>Thea</i>	Tea Tree
		<i>Theobroma</i>	Chocolate Nut Tree
<i>Saccharum</i>	Sugar Cane	<i>Thuja</i>	Arbor Vitæ, &c.
<i>Salix</i>	Willow Tree, Osier	<i>Thymbra</i>	Mountain Hyssop
<i>Salsola</i>	Shrubby Saltwort, Stonecrop Tree	<i>Thymus</i>	Thyme
<i>Salvia</i>	Sage	<i>Tilia</i>	Lime Tree
<i>Sambucus</i>	Elder Tree	<i>Tinus</i>	Tinus, or Tree Volkameria
<i>Sanguinaria</i>	Puccoon, Bloodwort	<i>Tolujera</i>	Balsam of Tolu Tree
<i>Santolina</i>	Lavender Cotton	<i>Tournefortia</i>	Tournefortia
<i>Sapindus</i>	Soap-berry Tree	<i>Trachelium</i>	Throatwort
<i>Saponaria</i>	Soapwort	<i>Tradescantia</i>	Virginian Spiderwort
<i>Sarracenia</i>	Saddle Flower	<i>Tragopogon</i>	Goat's Beard, Salsafy
<i>Saturcia</i>	Savory	<i>Trillium</i>	Trillium
<i>Satyrium</i>	Satyrium, or Lizard-flower	<i>Triumfetta</i>	Triumfetta
<i>Saxifraga</i>	Saxifrage	<i>Tropæolum</i>	Nasturtium, or Indian Cress
<i>Scabiosa</i>	Scabious	<i>Tulipa</i>	Tulip
<i>Scandix</i>	Garden Chervil	<i>Turnera</i>	Turnera
<i>Schinus</i>	Mastic Tree		
<i>Scilla</i>	Squill	<i>Ulex</i>	Furze, Gorse, or Whins
<i>Scorpiurus</i>	Caterpillar Plant	<i>Ulmus</i>	Elm Tree
<i>Scorzonera</i>	Viper's Grass, Spanish Scorzonera	<i>Urena</i>	Indian Mallow
<i>Scrophularia</i>	Figwort		
<i>Scutellaria</i>	Skull-cap	<i>Valeriana</i>	Valerian
<i>Sedum</i>	Stonecrop, Houseleek	<i>Veratrum</i>	Hellebore
<i>Selago</i>	Selago	<i>Verbascum</i>	Mullein
<i>Sempervivum</i>	Houseleek, Tree Sedum	<i>Verbena</i>	Vervain
<i>Senecio</i>	Groundsel	<i>Verbesina</i>	Indian Hemp Agrimony
<i>Serratula</i>	Saw-wort	<i>Veronica</i>	Veronica, Speedwell
<i>Sida</i>	Sida, Indian Mallow	<i>Viburnum</i>	Wayfaring Tree, Guelder Rose, Laurustinus
<i>Sideritis</i>	Iron-wort		
<i>Sideroxylon</i>	Iron-wood	<i>Vicia</i>	Garden Bean
<i>Silene</i>	Catchfly	<i>Vinca</i>	Periwinkle
<i>Silphium</i>	Silphium	<i>Viola</i>	Violet, Heart's Ease
<i>Sinapis</i>	Mustard	<i>Vitis</i>	Chaste Tree
<i>Sisymbrium</i>	Water-cress	<i>Vitis</i>	Vine Tree
<i>Sisyrinchium</i>	Sisyrinchium	<i>Volkameria</i>	Volkameria
<i>Smilax</i>	Skirret		
<i>Smilax</i>	Smilax	<i>Wachendorfia</i>	Wachendorfia
<i>Smyrniolum</i>	Common Alexanders	<i>Waltheria</i>	Waltheria
<i>Solanum</i>	Nightshade, Love Apple, Potatoe	<i>Wintera</i>	Winterana
<i>Soldanella</i>	Soldanella		
<i>Solidago</i>	Golden Rod	<i>Xanthemum</i>	Eternal Flower
<i>Sophora</i>	Sophora	<i>Xylophylla</i>	Love Flower
<i>Sorbus</i>	Mountain Service, Mountain Ash, &c.		
<i>Spartium</i>	Broom	<i>Yucca</i>	Adam's Needle
<i>Spermacoe</i>	Button-weed		
<i>Spinacia</i>	Garden Spinach	<i>Zanthoxylum</i>	Tooth-ach Tree
<i>Spiraea</i>	Spirea	<i>Zea</i>	Maize, or Indian Corn
<i>Sporobolus</i>	Hog Plant	<i>Zinnia</i>	Zinnia
<i>Stapelia</i>	Stapelia	<i>Zygophyllum</i>	Bean Caper

ENGLISH NAMES OF THE PLANTS.

A BELE Tree	<i>Populus</i>	Arbutus, Dwarf	<i>Arbutus</i>
Acacia	<i>Mimosa</i>	Arbutus, Trailing	<i>Epigaea</i>
Acacia, False	<i>Robinia</i>	Artichoke	<i>Cynara</i>
Acacia, Scarlet	<i>Robinia</i>	Artichoke, Jerusalem	<i>Helianthus</i>
Acacia, Three-thorned	<i>Gleditsia</i>	Arum, African	<i>Calla</i>
Acajou	<i>Anacardium</i>	Asarabacca	<i>Asarum</i>
Aconite	<i>Aconitum</i>	Ash Tree	<i>Fraxinus</i>
Aconite, Winter	<i>Helleborus</i>	Ash, Mountain	<i>Sorbus</i>
African Marigold	<i>Tagetes</i>	Ash, Poison	<i>Rhus</i>
Agaric	<i>Agaricus</i>	Asparagus	<i>Asparagus</i>
Agrimony	<i>Agrimonia</i>	Aspen Tree	<i>Populus</i>
Agrimony, Hemp	<i>Eupatorium</i>	Asphodel	<i>Asphodelus</i>
Alaternus	<i>Rhamnus</i>	Asphodel, African	<i>Anthericum</i>
Alaternus, Bastard	<i>Phytica</i>	Asphodel, Lily	<i>Crinum</i>
Alder Tree	<i>Betula</i>	Asphodel, Lily	<i>Heimerocallis</i>
Alder, Berry-bearing	<i>Rhamnus</i>	Atamasca, Lily	<i>Amaryllis</i>
Alexanders	<i>Smyrnum</i>	Avens	<i>Cicum</i>
Alkekengi	<i>Physalis</i>	Avogate Pear	<i>Laurus</i>
All-spice	<i>Myrtus</i>	Auricula	<i>Primula</i>
Alligator Pear	<i>Laurus</i>	Azarole	<i>Crategus</i>
Almond Tree	<i>Amygdalus</i>		
Aloe, African	<i>Aloe</i>	Balm	<i>Melissa</i>
Aloe, American	<i>Agave</i>	Balm of Gilead	<i>Dracocephalum</i>
Althaea Frutex	<i>Hibiscus</i>	Balsam, or Balsamine	<i>Impatiens</i>
Alysson	<i>Alyssum</i>	Balsam Apple, Male	<i>Momordica</i>
Amaranth	<i>Amaranthus</i>	Balsam Tree	<i>Clusia</i>
Amaranthus, Cock's-comb	<i>Celasia</i>	Balsam Tree	<i>Pistacia</i>
Amaranthus, Globe	<i>Gomphrena</i>	Balsam of Gilead Tree	<i>Amyris</i>
Amber Tree	<i>Anthospermum</i>	Balsam of Capivi Tree	<i>Copaifera</i>
Amelanchier	<i>Mespilus</i>	Balsam of Mecca Tree	<i>Amyris</i>
Amellus	<i>Aster</i>	Balsamine, Female	<i>Impatiens</i>
Ananas	<i>Bromelia</i>	Bamboo Cane	<i>Arundo</i>
Andrachne	<i>Arbutus</i>	Banana Tree	<i>Musa</i>
Andromeda	<i>Andromeda</i>	Bane Berries	<i>Actea</i>
Anemone	<i>Anemone</i>	Barba Jovis	<i>Anthyllis</i>
Angelica	<i>Angelica</i>	Bark, False Jesuit's	<i>Ioa</i>
Angelica, Berry-bearing	<i>Aralia</i>	Barren Wort	<i>Epimedium</i>
Angelica Tree	<i>Aralia</i>	Base Trefoil	<i>Cytisus</i>
Anotta	<i>Bixa</i>	Bachelor's Button	<i>Lychnis</i>
Apple Tree	<i>Pyrus</i>	Bay Tree	<i>Laurus</i>
Apple, Custard	<i>Annona</i>	Bay, Loblolly	<i>Gordonia</i>
Apple, Love	<i>Solanum</i>	Bay, Rose	<i>Verum</i>
Apple, Mad	<i>Solanum</i>	Bay, Dwarf Rose	<i>Rhododendrum</i>
Apple, Male Balsam	<i>Momordica</i>	Bay, Plum	<i>Psidium</i>
Apple, Pine	<i>Bromelia</i>	Bead Tree	<i>Melia</i>
Apple, Soap	<i>Sapindus</i>	Bean, Common	<i>Vicia</i>
Apple, Star	<i>Chrysophyllum</i>	Bean, Kidney	<i>Phaseolus</i>
Apple, Sweet	<i>Annona</i>	Bean Tree, Kidney	<i>Glycine</i>
Apple, Thora	<i>Datura</i>	Bean Trefoil, Stinking	<i>Anagyris</i>
Apricot Tree	<i>Prunus</i>	Bearberries	<i>Arbutus</i>
Arbutus	<i>Arbutus</i>	Bearbind	<i>Convolvulus</i>

INDEX TO ENGLISH NAMES OF THE PLANTS.

Bear's Breech	<i>Acanthus</i>	Button Weed	<i>Spermacoce</i>
Bear's Ear	<i>Primula</i>	Cabbage	<i>Brassica</i>
Bear's Ear, Sarcile	<i>Cortusa</i>	Cabbage, Sea	<i>Crambe</i>
Bear's Foot	<i>Helleborus</i>	Cabbage Tree	<i>Areca</i>
Beard, Old-man's	<i>Clematis</i>	Cabbage Tree	<i>Cacalia</i>
Beard, Jupiter's	<i>Anthyllis</i>	Cabbage, Turnip	<i>Brassica</i>
Bee Flower	<i>Ophrys</i>	Calabash	<i>Cucurbita</i>
Bee Larkspur	<i>Delphinium</i>	Calabash Tree	<i>Crescentia</i>
Beech Tree	<i>Fagus</i>	Calamint	<i>Melissa</i>
Beet	<i>Beta</i>	Calamint, Water	<i>Mentha</i>
Bell Flower	<i>Campanula</i>	Calves' Snout	<i>Antirrhinum</i>
Bell Flower, Canary	<i>Canarina</i>	Campeachy Wood	<i>Hemutorylum</i>
Bells, Canterbury	<i>Campanula</i>	Camphor Tree	<i>Laurus</i>
Bell, Hare	<i>Hyacinthus</i>	Campion, Rose	<i>Agrostemma</i>
Bell-Pepper	<i>Capicum</i>	Campion	<i>Lychnis</i>
Belladonna Lily	<i>Amaryllis</i>	Campion, Viscous	<i>Silene</i>
Belvidere	<i>Chenopodium</i>	Canary Bell-Flower	<i>Canarina</i>
Benjamin Tree	<i>Laurus</i>	Candleberry Myrtle	<i>Myrica</i>
Bennet, Herb	<i>Geum</i>	Candy Lion's-Foot	<i>Catananche</i>
Berberry	<i>Berberis</i>	Candy-Tuft	<i>Iberis</i>
Bind-weed	<i>Convolvulus</i>	Candy-Tuft Tree	<i>Iberis</i>
Bind-weed, Rough	<i>Smilax</i>	Cane Reed	<i>Arundo</i>
Bind-weed, Black	<i>Tamus</i>	Cane, Sugar	<i>Saccharum</i>
Birch Tree	<i>Betula</i>	Canterbury Bells	<i>Campanula</i>
Bird Cherry	<i>Prunus</i>	Caper Bush	<i>Capparis</i>
Bird Pepper	<i>Capicum</i>	Caraway	<i>Carum</i>
Bird's Eye	<i>Adonis</i>	Caragana	<i>Robinia</i>
Bird's-foot Trefoil	<i>Lotus</i>	Cardinal Flower	<i>Lobelia</i>
Bird's Nest	<i>Ophrys</i>	Cardoon	<i>Cynara</i>
Bird's Nest, Purple	<i>Orchis</i>	Carnation	<i>Dianthus</i>
Bird's Service	<i>Sorbus</i>	Caruation Tree	<i>Cacalia</i>
Birthwort	<i>Aristolochia</i>	Carob Tree	<i>Cerutonia</i>
Bitter Vetch	<i>Orobus</i>	Carrot	<i>Daucus</i>
Bitter Wort	<i>Gentiana</i>	Carui	<i>Carum</i>
Bladder Nut	<i>Staphylea</i>	Cashew Nut	<i>Anacardium</i>
Bladder Sena	<i>Colutea</i>	Cassava	<i>Jatropha</i>
Bladder Sena, Jointed-podded	<i>Coronilla</i>	Cassia, Poet's	<i>Oxyris</i>
Blite	<i>Blitum</i>	Cassidony	<i>Gnaphalium</i>
Blood Flower	<i>Hemantus</i>	Catalpa	<i>Bignonia</i>
Blood Wood	<i>Hematoxylum</i>	Catchfly	<i>Lychnis</i>
Blood Wort	<i>Rumex</i>	Catchfly, Lobel's	<i>Silene</i>
Bloody Dock	<i>Rumex</i>	Catchfly, German	<i>Lychnis</i>
Blue Bottle	<i>Centaurea</i>	Caterpillar Plant	<i>Scorpiurus</i>
Bonduc Tree	<i>Guilandina</i>	Caterpillar Trefoil	<i>Medicago</i>
Borecole	<i>Brassica</i>	Cat-Mint	<i>Nepeta</i>
Borage	<i>Borago</i>	Cauliflower	<i>Brassica</i>
Bottle Flower	<i>Centaurea</i>	Cedar, Barbadoes	<i>Cedrela</i>
Box Tree	<i>Burns</i>	Cedar, Bermudas	<i>Juniperus</i>
Box Tree, African	<i>Myrsine</i>	Cedar, Carolina	<i>Juniperus</i>
Box Thorn	<i>Lycium</i>	Cedar, Lebanon	<i>Pinus Cedrus</i>
Box Thorn, Ethiopian	<i>Celastrus</i>	Cedar, Lycian	<i>Juniperus</i>
Bramble	<i>Rubus</i>	Cedar, Phœnician	<i>Juniperus</i>
Brank, Ursine	<i>Acanthus</i>	Cedar, Virginian	<i>Juniperus</i>
Bread-Fruit Tree	<i>Artocarpus</i>	Cedar, White	<i>Cupressus</i>
Break-Stone	<i>Saxifraga</i>	Celandine	<i>Cheridonium</i>
Brocoli	<i>Brassica</i>	Celandine Tree	<i>Boconia</i>
Broom	<i>Spartium</i>	Celeriac	<i>Apium</i>
Broom, African	<i>Aspalathus</i>	Celery	<i>Apium</i>
Broom, Dyer's	<i>Gouista</i>	Centaury	<i>Centaurea</i>
Broom, Spanish	<i>Spartium</i>	Cereus	<i>Cactus</i>
Broom, Butcher's	<i>Ruscus</i>	Chanomile	<i>Anthemis</i>
Bryony, Black	<i>Tamus</i>	Chardon (Cardoon)	<i>Cynara</i>
Buckthorn	<i>Rhamnus</i>	Chaste Tree	<i>Viter</i>
Buckthorn, Sea	<i>Hippophae</i>	Cherry Tree	<i>Prunus</i>
Bugle	<i>Ajuga</i>	Cherry, Barbadoes	<i>Mulpighia</i>
Bugloss	<i>Achusa</i>	Cherry, Bird	<i>Prunus</i>
Bullace Tree	<i>Prunus</i>	Cherry, Cornelian	<i>Cornus</i>
Burnet, Garden	<i>Poterium</i>	Cherry, Dwarf	<i>Lonicera</i>
Burning Thorny Plant	<i>Euphorbia</i>	Cherry, Double-blossom	<i>Prunus</i>
Butcher's Broom	<i>Ruscus</i>	Cherry, Hottentot	<i>Cassia</i>
Button Tree	<i>Cephalanthus</i>		

INDEX TO ENGLISH NAMES OF THE PLANTS.

Cherry, Laurel	<i>Prunus</i>	Cowslip	<i>Primula</i>
Cherry, Winter	<i>Physalis</i>	Cowslip, Virginian	<i>Dodecatheon</i>
Cherry, Winter	<i>Solanum</i>	Crab Tree	<i>Pyrus</i>
Cherry, Plum	<i>Prunus</i>	Crab, Siberian	<i>Pyrus</i>
Chervil, Garden	<i>Scandix</i>	Crane's Bill	<i>Geranium</i>
Chervil, Great Perennial	<i>Scandix</i>	Crane's Bill, Shrubby African	<i>Pelargonium</i>
Chesnut Tree	<i>Fagus</i>	Creeper, Virginian	<i>Hedera</i>
Chesnut, Horse	<i>Esculus</i>	Cress, Garden	<i>Lepidium</i>
China-Aster	<i>Aster</i>	Cress, Indian	<i>Tropaeolum</i>
China-Root	<i>Smilax</i>	Cress, Water	<i>Sisymbrium</i>
China Pink	<i>Dianthus</i>	Crocus, Spring	<i>Crocus</i>
China Rose	<i>Hibiscus</i>	Crocus, Autumn	<i>Crocus</i>
Chinquapin	<i>Fagus</i>	Crocus, Saffron	<i>Crocus</i>

INDEX

TO THE

GARDEN-APPARATUS, BUILDINGS, &c. REPRESENTED IN THE PLATES.

VOL. I.

- PLATE A.** Fig. 1. Mushroom Bed.—Fig. 2. Improved Bark-Pit.—Fig. 3. Section of—Fig. 4. Common Bark-Pit.—Fig. 5. Small Bark-Pit.
- B.** An Improved Conservatory.—Fig. 1. End Elevation.—Fig. 2. Section of Do.—Fig. 3. Longitudinal Section of Back-Wall.
- C.** Fig. 1. Ground Plan of Conservatory.—Fig. 2. Front Elevation of Do.
- D.** An Improved Cucumber-Frame.—Fig. 1. Ground Plan.—Fig. 2. Front Elevation.—Fig. 3. End Elevation.—Fig. 4. Longitudinal Section.—Fig. 5. Section showing Bark-Pit.—Fig. 6. Section showing Flue.
- E.** An Improved Melon-Frame or Pit.—Fig. 1. Ground Plan.—Fig. 2. Front Elevation.—Fig. 3. Section across the Bed.
- F.** A Plan for laying out Gardens in the most improved Manner.
- G.** An Improved Hothouse.—Fig. 1. Section showing Fire-Place and Construction of Flues, so as to produce the proper Heat with the least possible Con-

sumption of Fuel.—Fig. 2. is the Ground Plan.—Fig. 3. A Section showing the Form of the Bark-Pit, &c.

- PLATE H.** An Improved Hot-Wall.—Fig. 1. Ground Plan of Wall and Back-Shed.—Fig. 2. Longitudinal Section showing the Passage of the Flue.—Fig. 3. Section across the Wall.

VOL. II.

- A.** Fig. 1. Section of Improved Ice-House.—Fig. 2. Plan of Well on Level of Passage-Floor.—Fig. 3. Lower Plan of Well.—Fig. 4. Front Elevation of Entrance.
- B.** An Improved Stove, Peach and Succession-House.
- C.** Section and End Elevation of Hothouse, &c.—Fig. 1. and 2. Sections.—Fig. 3. End Elevation.
- D.** An Improved Vinery.—Fig. 1. shows the Front Elevation.—Fig. 2. is a Section of the End.—Fig. 3. is a Section showing the Flues.—Fig. 4. is the Plan.
- E.** Improved Implements of Gardening.
